3. For the discontinuation of anti-TNF- α therapy: in nonresponders, consideration should be made after 6-12 weeks' treatment. Response is defined as improvement of
 - (a) at least 50% or 2 units (on a 0-10 scale) of the BASDAI
 - (b) expert opinion that treatment should be continued

patients will seek surgical correction of their spinal deformities. In general, open, polysegmental, and closing wedge osteotomies are employed. Loss of correction is seen least commonly in closing wedge osteotomy. In a meta-analysis of the literature between 1945 and 1998, an average correction of 37–40° degrees was seen, with perioperative mortality of 4% due to pulmonary, cardiac, and intestinal problems.⁴⁰

CONCLUSION

Great progress has been made in the classification and epidemiology of SpA, particularly in the elucidation of the factors involved in the SpA pathogenesis in recent years. It has become clear that HLA-B27, the primary genetic factor identified in the pathogenesis of SpA, functions in a variety of roles, including 'classical' antigen presentation. How these lead to disease remains to be seen. Genome-wide scans have identified a number of regions that may contain other susceptibility genes for SpA, and these are being examined. Non-MHC genes that contribute to SpA susceptibility are currently being elucidated and a number of promising candidates have been identified.

On the other hand, less recent progress has been made in nongenetic factors. Despite what has been learned in ReA, no infectious trigger has been identified in AS (and in fact there might be no specific trigger). The link of gut inflammation to the triggering of AS is strongly suggested by data thus far, but has still not been defined. This is clearly an area of promise for further investigation.

Novel outcome measures have been developed that will help us to care better for our patients, especially in the area of imaging. Most exciting has been the advances in treatment, particularly in the development of biologic treatments, which hold promise for a better future for patients with these diseases.

Small- and medium-vessel primary vasculitis

John H. Stone, David B. Hellmann

58

Vasculitis is defined as inflammation within blood vessel walls. Inflamed blood vessels are liable to narrow, thrombose, or rupture, and thereby cause tissues served by those vessels to undergo ischemic damage. The many different forms of vasculitis offer several challenges. First, these diseases often begin with nonspecific symptoms and signs, unfolding in an enigmatic fashion. Thus, vasculitis is one of the great diagnostic challenges in medicine. Knowledge of the clinical disguises by which vasculitis can present often permits the physician to suspect or diagnose the condition at the bedside. Second, with therapy, most patients improve, some enter disease remissions, and a substantial portion – variable according to disease type – are cured. Treating patients with vasculitis can therefore be even more rewarding than making the diagnosis. Finally, rapidly expanding knowledge of the pathophysiology of vasculitides promises more specific and more effective therapies for these diseases in the near future.

CLASSIFICATION OF VASCULITIS

More than 20 different forms of vasculitis are recognized; because the causes of most forms are not known, the vasculitides are distinguished by their clinicopathologic differences.¹ Classification schemes have traditionally categorized the different forms of vasculitis according to the size of blood vessels affected (Table 58.1). Beyond vessel size, the vasculitides can also be distinguished by considerations such as the typical host, the organs most commonly affected, and the presence of certain pathologic features. For example, within the small-vessel vasculitides, Henoch–Schönlein purpura (HSP) most commonly occurs in children, typically affects the gut, skin, joints, and kidneys, and produces vasculitis characterized by deposition of immunoglobulin A (IgA). In contrast, Wegener's granulomatosis (WG) usually strikes adults, has a predilection for the upper airways, lungs, and kidneys, and causes granulomatous inflammation. Finally, disorders in which vasculitis is the central cause of the symptoms and signs are designated 'primary.' 'Secondary' forms of vasculitides are those in which vasculitis complicates another type of disease, such as systemic lupus erythematosus (SLE) (Chapter 51) or rheumatoid arthritis (RA) (Chapter 52). This chapter focuses on primary vasculitides.

PATHOGENESIS

With few exceptions among the vasculitides, the etiologies of these diseases are not known, and precise knowledge of how the various effector cells of the immune system, the endothelial cells, cytokines, and other mediators interact to cause vascular inflammation is incomplete. Nevertheless, discussion of what is known about a few forms of vasculitis provides a framework for considering how perturbations of the immune system might play a role. The mechanisms described below are models of disease pathophysiology that have been proposed to explain anti-neutrophil cytoplasmic antibody (ANCA)-associated and immune complex (IC)-mediated vasculitis, respectively.

ANCA MODEL

ANCA are directed against different enzymes contained within primary granules of neutrophils and macrophages. These antibodies are usually detected by adding a patient's serum to a preparation of neutrophils, followed by the addition of an antibody tagged with a fluorescent label. In vasculitis, two main patterns of immunofluorescence (IF) are seen: a cytoplasmic pattern (C-ANCA) (Fig. 58.1) or a perinuclear pattern (P-ANCA). The C-ANCA pattern, usually caused by antibodies to serine proteinase 3 (PR-3), is highly specific for WG.² The P-ANCA pattern, typically caused by antibodies to myeloperoxidase (MPO), is much less specific, being found in some patients with WG, microscopic polyangiitis (MPA), the Churg–Strauss syndrome (CSS), and other diagnoses.

Two murine models of ANCA-associated vasculitis (AAV) reveal that adoptive transfer of autoantibody alone is sufficient to induce a necrotizing vasculitis that closely resembles human disease. These models involved two types of genetically altered mice: the MPO knockout mouse and the recombina-activating gene 2 (RAG-2)-deficient mouse. The latter species lacks both T and B cells. These models provide *in vivo* evidence for the pathogenic potential of ANCA. In the MPO knockout model,³ mice were initially immunized with mouse MPO, resulting in the formation of anti-MPO T cells and B cells and anti-MPO antibodies. RAG-2-deficient mice were subsequently injected with either anti-MPO

Table 58.1 Major categories of primary vasculitis**Large-vessel vasculitis**

Giant-cell arteritis
Takayasu's arteritis

Medium-vessel vasculitis

Polyarteritis nodosa
Kawasaki's disease
Primary central nervous system vasculitis
Buerger's disease

Small-vessel vasculitis

Anti-neutrophil cytoplasmic antibody (ANCA)-associated small-vessel vasculitis:

- Microscopic polyangiitis
- Wegener's granulomatosis
- Churg–Strauss syndrome
- Drug-induced ANCA-associated vasculitis

Immune-complex small-vessel vasculitis:

- Hypersensitivity vasculitis
- Cryoglobulinemic vasculitis
- Connective tissue disorders
- Urticarial vasculitis
- Behçet's disease
- Goodpasture's syndrome
- Serum sickness
- Infection-induced vasculitis

Paraneoplastic small-vessel vasculitis
Inflammatory bowel disease vasculitis

splenocytes or control splenocytes, which did not produce anti-MPO antibodies. RAG-2 mice that received anti-MPO splenocytes developed clinical features of AAV, including crescentic glomerulonephritis and systemic necrotizing vasculitis. By comparison, RAG-2 mice that received non-MPO antibody-producing splenocytes displayed only a relatively mild IC glomerulonephritis. In the RAG-2 model, RAG-2-deficient and wild-type mice were injected with anti-MPO or control immunoglobulins. Only mice receiving anti-MPO antibodies developed a pauci-immune glomerulonephritis.

Potential disease triggers in humans

For AAV in humans, a variety of infectious, genetic, and environmental risk factors (and combinations of all three) have been considered as triggers. Because the symptoms of WG at disease onset overlap substantially with those due to infectious processes, research efforts have focused upon the identification of pathogens that may precipitate WG in individuals of the proper genetic background. However, attempts to identify an infectious cause or causes for WG have not been fruitful. Efforts to define genetic risk factors have also met with limited success.^{4–6}

Fig. 58.1 Anti-neutrophil cytoplasmic antibody (ANCA) patterns. **(A)** Immunofluorescence study of serum on the substrate of human neutrophils, demonstrating cytoplasmic immunofluorescence (a positive ANCA assay, C-ANCA pattern). **(B)** Perinuclear immunofluorescence (P-ANCA pattern).

Given the frequency with which the first symptoms of WG occur in the respiratory tract, exposure to noninfectious agents or toxins via the inhalational route is another possible inciting event. One such candidate is silica dust. The odds ratio of exposure to silica dust has been reported to be 4.4 times higher for patients with AAV than in a comparison group of patients with renal disease caused by lupus or other conditions.⁷ However, exact relationships between environmental exposures and vasculitis are complicated by difficulties in obtaining reliable measurements of exposures, the likelihood of recall bias among patients who are diagnosed with AAV, and the choice of appropriate control groups.

Because alpha-1 antitrypsin (AAT) is the primary *in vivo* inhibitor of PR-3, the observation that patients with AAT deficiency are at increased risk for WG suggests a potential pathogenic role in this disease for deficient PR-3 clearance from sites of inflammation.^{8,9} Decreased local

concentrations of AAT caused by genetic polymorphisms or alterations in the enzyme's functionality induced by inflammation may therefore lead to protease/antiprotease imbalance in the disease microenvironment. Although unproven, these events may be responsible for generating immunogenic forms of PR-3 in these patients.

Mechanisms of ANCA production

Autoantibodies reactive to ANCA are probably generated against newly exposed epitopes (i.e., cryptic sites) of the target autoantigen. Following the production of ANCA, the antibody response may generalize to the rest of the molecule or to other components of a macromolecular protein complex via the process of epitope spreading. With WG, these neoepitopes may arise at the sites of initial tissue injury. Since it is an antigen-driven process, the disease may heavily depend upon help from T cells.

This hypothesis is supported by the finding that lymphocytes have a significant role in AAV:

- Patients with active WG have much higher levels of activated CD4 T cells and monocytes than do patients in remission or healthy controls.¹⁰
- Very high levels of the Th1 cytokines tumor necrosis factor- α (TNF- α) and interferon (IFN)- γ are observed in patients with active WG. Monocytes from these patients release large quantities of interleukin-12 (IL-12), a major inducer of Th1 cytokines.
- Population-based studies of WG patients reveal a diminished frequency of a major inhibitory CTLA-4 allele.¹¹ This may contribute to increased T-cell activation in these patients.

These findings suggest that IL-10, a known antagonist of monocyte activation, may inhibit the Th1 pathway in this disease by impairing the production of IL-12. In one study, for example, IL-10 treatment of peripheral blood mononuclear cells from active WG patients impaired the production of IFN- γ *in vitro*.¹⁰

The roles of ANCA isotypes and Fc receptors

In theory, the isotype of ANCA in a given individual may have pathophysiological importance. Most patients with AAV, for example, produce isotype-switched IgG ANCA, implying a T-cell-dependent immune response. However, studies regarding the relative importance of IgG subtypes and other types of ANCA (e.g., IgM, IgA) have been inconclusive and contradictory. Presently, there is no clear evidence that particular ANCA isotypes influence the susceptibility to or clinical expression of AAV. The magnitude of enhanced neutrophil activation by ANCA may also be influenced by antibody specificity for different PR-3 epitopes, IgG subclass, and the type of Fc γ -R engaged. The Fc γ -RIIIB allele polymorphism NA1, which allows more efficient neutrophil activation by ANCA, is overrepresented in patients with severe forms of WG.¹²

ANCA and neutrophil activation

The significant role described above for lymphocytes in AAV does not exclude an important role for ANCA themselves. Because Th1 cytokines are effective stimuli of both neutrophils and monocytes, the production of ANCA may further enhance tissue injury by augmenting the damage

caused by mononuclear cells. The effects of ANCA are determined by the state of neutrophil activation. PR-3 and MPO, located in the cytosol, can be relatively inaccessible to antibody binding. However, neutrophils primed with TNF as well as those undergoing apoptosis express increased quantities of membrane-associated PR-3,^{13, 14} a process known as neutrophil 'priming.' In some individuals, a higher proportion of nonactivated neutrophils may express membrane-associated PR-3, which may be a risk factor for vasculitis, or for more severe manifestations of vasculitis.

Once neutrophils have been activated by priming, ANCA are able to bind relevant membrane-bound antigens, causing abnormal constitutive activation via either the cross-linking of MPO or PR-3 or the binding of Fc receptors. Persistent ANCA binding to neutrophils on the endothelial surface can enhance the degree of vascular injury. The rate at which primed neutrophils degranulate and release chemoattractants and cytotoxic oxygen free-radical species into the local tissue environment is also increased by ANCA. In addition, primed neutrophils can adhere to and damage vascular endothelial cells and attract additional neutrophils to the site of damage, thereby creating an auto-amplifying loop.

Patients with AAV have increased numbers of primed neutrophils in renal biopsy specimens, paralleling the activity of the disease. In addition, persistent membrane expression of PR-3 during periods of disease remission is associated with an increased risk of relapse in WG patients. Enhanced generation of reactive oxygen species by circulating neutrophils in these patients compared to controls may also occur.

ANCA-associated activation can induce neutrophil actin polymerization, resulting in increased neutrophil rigidity.¹⁵ Such activated neutrophils can become sequestered in small-sized vessels since they are unable to adapt morphologically to arterioles; this may help explain the predilection for small blood vessels in ANCA-associated disease.

Role of the endothelial cell

Whether endothelial cells produce PR-3 and display this molecule upon activation is controversial. In the early stages of AAV, however, endothelial cells are known to recruit inflammatory cells and enhance their adhesion to sites of vascular injury. The subsequent release of PR-3 (from infiltrating leukocytes, at a minimum) and other neutrophil proteases may induce endothelial synthesis and secretion of IL-8, a potent neutrophil chemoattractant, thereby attracting additional neutrophils. PR-3 released by neutrophils can also enhance the adhesion of accumulating neutrophils and mononuclear cells to the endothelial surface via the induction of adhesion molecules, such as vascular cell adhesion molecule-1 (VCAM-1). VCAM-1 is known to be expressed *in situ* within the renal lesions of patients with AAV. The soluble endothelial protein C receptor binds activated neutrophils via interactions with PR-3, providing a link between neutrophil priming, vascular inflammation, and the coagulation cascade. This may explain, in part, the increased risk of venous thrombotic events observed in WG.¹⁶ Organ-specific anti-endothelial antibodies have also been reported, albeit the precise antigens and role in disease development are unclear.

The role of B cells

B cells may also play an important role in AAV. The number of activated B cells in circulation correlates with disease activity scores in AAV.¹⁷ Furthermore, B-cell depletion therapy in AAV has shown encouraging results.^{18, 19} The rationale for why B-cell depletion may be effective in

AAV is not clear, but possibilities include the complete removal or substantial reduction of ANCA production; diminution of the contribution of B cells to antigen presentation and cytokine production; and the inhibition of B-cell/T-cell cross-talk.

IMMUNE COMPLEX MODEL

Another established mechanism for causing vasculitis is the deposition of circulating ICs. ICs are known to contribute substantially to a number of types of vasculitis in humans. IC deposition is thought to be the prevailing disease mechanism, for example, in HSP, hypersensitivity vasculitis, mixed cryoglobulinemia, and hepatitis B-associated polyarteritis nodosa (PAN). After the formation of soluble ICs, the complexes are deposited in the subendothelium, an event facilitated by the release of vasoactive amines (e.g., histamine) from platelets and basophils. Once trapped in the subendothelial space, ICs fix complement and generate chemotactic factors for the recruitment and activation of neutrophils. Degranulation of these neutrophils leads to the release of oxygen radicals and lysosomal enzymes, which in turn damage the blood vessel walls.

The IC model is compatible with the transient vasculitis known as serum sickness that develops following exposure to some foreign antigens. Antigens as varied as the horse serum formerly used in immunizations, antibiotics (e.g., penicillin), virus-associated antigens (e.g., hepatitis B or C) or self-antigens (e.g., double-stranded DNA) are capable of causing IC-mediated vasculitis in humans. In cases involving a 'one-shot' antigen exposure, the vasculitis resolves as the antigen is cleared. However, when the antigen persists, e.g., in chronic viral hepatitis, SLE, or RA, the vasculitis can be chronic (albeit the precise antigen is not always known).

Formation of ICs is common, even in healthy individuals, but the occurrence of vasculitis is relatively rare. Several factors determine the pathogenicity of ICs. Antigen load is one determinant, as only amounts of antigen large enough to overwhelm the reticuloendothelial system (RES) provoke a pathologic IC response. Another important factor is solubility of the IC, which changes with the ratio of antigen to antibody. When the antigen-to-antibody ratio is very high, for example, complexes of antibody and antigen do not form. Conversely, when antibody is present in large excess compared to the antigen, the RES clears the antigen rapidly. ICs formed in slight antigen excess are most likely to be pathogenic, because they are both soluble and of sufficient size to deposit in blood vessel walls. Finally, physical forces such as pressure within the blood vessel (which can damage vessels), temperature (certain ICs such as cryoglobulin form at colder temperatures), or locations of vascular branch points (where turbulence favors IC deposition) can influence the development of vasculitis.

GENERAL CLUES TO DETECTING VASCULITIS

Inflamed vessels produce clinical symptoms and signs either by being associated with the release of inflammatory cytokines that cause malaise, fever, and weight loss, or by causing direct ischemic damage to specific tissues, such as the induction of digital gangrene. Since the vasculitides demonstrate predilections for certain tissues and organs, their presenting manifestations vary greatly. However, most of the vasculitides share four general features: first, they unfold in a subacute fashion, over weeks or months; second, pain is often a prominent feature of a vasculitis, be it from mononeuritis multiplex, scleritis, migratory oligoarthritis/arthritis, myalgias, mesenteric ischemia, or another consequence of vascular

CLINICAL PEARLS

GENERAL CLUES TO DETECTING VASCULITIS

- >> Clinical symptoms and signs in vasculitis relate to:
 - The release of inflammatory cytokines that cause malaise, fever, and weight loss
 - Direct ischemic damage to specific tissues
- >> Most of the vasculitides share four general features:
 - Disease manifestations usually unfold in a subacute fashion, over weeks or months
 - Pain is often a prominent feature
- >> Signs of inflammation, such as fever, rashes, and arthritis are prominent
- >> Evidence of multiorgan system dysfunction is common

inflammation; third, signs of inflammation, such as fever, rashes, and weight loss are also prominent; fourth, evidence of multiorgan system dysfunction is common. Although not every case of vasculitis adheres strictly to all four of these guidelines, bearing these clues in mind helps clinicians to identify patients whose symptoms and signs may be caused by vasculitis.

THE ANCA-ASSOCIATED VASCULITIDES

In a landmark 1954 paper, Godman and Churg²⁰ noted similar pathological features among three clinically distinct disease entities: WG, MPA, and CSS. These diseases, Godman and Churg noted, 'group themselves into a compass, [ranging from] necrotizing and granulomatous processes with angiitis, through mixed forms, to vasculitis without granulomata.' Over the past 15 years WG, MPA, and CSS have become recognized as the cardinal forms of vasculitis associated with ANCA. They are commonly termed ANCA-associated vasculitides or AAV, although not all patients who meet the clinical definitions of these diseases have ANCA. The hallmarks of WG, MPA, and CSS are displayed in [Table 58.2](#).

SEROLOGIC TESTING FOR ANCA

Two types of ANCA tests, IF and enzyme immunoassay (EIA), are now in common use. IF tests are highly operator-dependent, require a high degree of experience for proper interpretation, and are not antigen-specific. They are, however, generally superior to EIA in terms of sensitivity. In contrast to IF assays, EIAs are antigen-specific and demonstrate substantially higher positive predictive values for AAV. A widely adopted strategy for optimizing the utility of ANCA tests, therefore, is to screen patients with potential AAV by IF testing, and then to perform EIAs on patients who test positively.²¹ Capture EIAs, available at some centers, do not have clear advantages over these other assays.

WG, MPA, and CSS have variable strengths of association with ANCA ([Table 58.2](#)). The strength of association for each disease is affected by several factors, including disease activity, disease extent, and intensity of therapy. Even in WG, the disease for which the association

Table 58.2 Hallmarks of Wegener's granulomatosis (WG), microscopic polyangiitis (MPA), and Churg–Strauss syndrome (CSS)

	WG	MPA	CSS
ANCA positive	80–90%	75%	50%
Typical immunofluorescence/	C-ANCA/PR-3	P-ANCA/MPO	P-ANCA/MPO
Enzyme immunoassay results			
Upper respiratory tract	Nasal septal perforation Saddle-nose deformity Subglottic stenosis	Mild	Nasal polyps Allergic rhinitis
Lung	Nodules Cavitary lesions	Alveolar hemorrhage	Asthma Fleeting infiltrates
Kidney	NCGN, occasional granulomatous features	NCGN	NCGN (severe renal disease unusual)
Distinguishing feature	Destructive upper airway disease	No granulomatous inflammation	Allergy Eosinophilia

(Adapted from Rao JY, Weinberger M, Oddone EZ, et al. The role of antineutrophil cytoplasmic antibody (C-ANCA) testing in the diagnosis of Wegener's granulomatosis. *Ann Intern Med* 1995; 123: 425.)
ANCA, anti-neutrophil cytoplasmic antibody; C-ANCA, cytoplasmic ANCA; MPO, myeloperoxidase; NCGN, necrotizing crescentic glomerulonephritis; P-ANCA, perinuclear ANCA; PR-3, proteinase 3.

CLINICAL PEARLS

VASCULITIDES ASSOCIATED WITH ANTI-NEUTROPHIL CYTOPLASMIC ANTIBODIES (ANCA)

- >> Wegener's granulomatosis (WG), microscopic polyangiitis (MPA), and the Churg–Strauss syndrome (CSS) have become recognized as the types of vasculitis associated with ANCA
- >> Shortcomings of reliance upon ANCA to define this group of complex diseases:
- >> Not all patients with these diseases have a positive test for ANCA
- >> A variety of systemic illnesses, including infections, malignancies, and other conditions, may be associated with a positive ANCA test, particularly when positive immunofluorescence tests are not confirmed by enzyme immunoassay
- >> Even when ANCA are present, they are unreliable indicators of disease activity

with ANCA is the strongest, most series indicate that 10–20% of patients with active, disseminated, and untreated disease are ANCA-negative. For WG patients with limited WG, defined as the absence of an immediate threat to either the function of a vital organ or the patient's life, 30% or more of patients lack ANCA. In MPA, estimates of ANCA positivity approximate 70%. Finally, although relatively few data exist regarding the prevalence of ANCA in CSS, several studies have indicated that only about 50% of such patients are ANCA-positive.

When carefully employed and properly interpreted, ANCA assays constitute an important, albeit imperfect, adjunct to diagnosis. In rare instances, in the setting of classic clinical presentations and highly consistent ANCA test results (e.g., C-ANCA IF and PR-3 ANCA), the combination of clinical findings and ANCA assays may preclude the need for tissue biopsies to confirm the diagnosis. Despite advances in ANCA testing techniques, however, histopathology remains the cornerstone of diagnosis in AAV. When the diagnosis is unconfirmed, all reasonable attempts to obtain a tissue diagnosis should be pursued.

With regard to predicting disease flares, several studies indicate that elevations in ANCA titers do not predict disease flares; i.e., the temporal relationship between an increase in ANCA and the development of a clinical disease flare is poor.^{22, 23} Moreover, disease flares may also occur in the absence of an ANCA titer elevation.

Saddle-nose deformity and a left sixth cranial nerve lesion (the latter caused by meningeal inflammation) in a patient with Wegener's granulomatosis. (Reproduced with permission from Jinnah H, Dixon A, Brat D, et al. Chronic meningitis with cranial neuropathies in Wegener's granulomatosis: case report and review of the literature. *Arthritis Rheum* 1997; 40: 573.)

In the following sections, each of the three major forms of AAV is discussed. Treatment strategies for these disorders are discussed together in the final part of this section.

WEGENER'S GRANULOMATOSIS

In 1936 a German pathologist, Friedrich Wegener, reported 3 patients in their mid-30s whose innocuous presentations were those of a 'common cold'.²⁴ Within 7 months, all had succumbed to systemic inflammatory illnesses that culminated in uremia. Three years later, Wegener provided a more detailed description of this disease, which he referred to as 'a peculiar rhinogenic granuloma with particular involvement of the arterial system and the kidney'.²⁵

Godman and Churg recognized the three pathologic hallmarks of WG²⁰: (1) necrotizing granulomas in the upper and/or lower respiratory tract; (2) necrotizing vasculitis affecting arteries or veins; and (3) segmental glomerulonephritis, associated with necrosis and thrombosis of capillary loops, with or without granulomatous lesions. WG is regarded as one of the most common forms of systemic necrotizing vasculitis, with an annual incidence of 8.5 cases/million.²⁶ Although the disease occurs in all races, there is a strong predilection for individuals of northern European heritage. Classic WG involves the upper respiratory tract, the lungs, and the kidneys, but distinctive features of this disease may also occur in the eye, ear, and other organs. Involvement of tissues as diverse as the prostate gland and meninges has been reported.

The numerous disease manifestations of WG throughout the respiratory tract have long engendered suspicion that the disease results from interactions between an inhaled microbial pathoallergen(s) and a susceptible host. Approximately 90% of patients with WG have nasal involvement.²⁷ The nasal manifestations of WG include crusting, bleeding, and obstruction. Cartilaginous inflammation may lead to nasal septal perforation and even to collapse of the nasal bridge, a condition known

as a saddle-nose deformity (Fig. 58.2). Most patients with nasal (or sinus) disease eventually develop secondary infections of these tissues.

Erosive sinus disease is highly characteristic of WG. Among the AAV, only WG is likely to cause destructive lesions of the bony sinuses. Subglottic stenosis, resulting from a peculiar predilection of WG to cause scarring inflammation in the region of the trachea inferior to the vocal cords, is a potentially disabling disease feature. Subglottic involvement is often asymptomatic and may manifest itself only as a subtle hoarseness. However, some patients present with the subacute onset of respiratory stridor. With time, airway scarring occurs, sometimes accompanied by profound tracheal narrowing. Severe cases require tracheostomy. Subglottic stenosis, particularly when associated with scarring and fibrosis, often responds poorly to immunosuppressive therapy. The most effective therapeutic approach to subglottic stenosis in these cases is usually mechanical, i.e., surgical dilations to enlarge the airway narrowing, combined with local glucocorticoid injections.

Two principal forms of ear disease, conductive and sensorineural hearing loss, are typical of WG. Mixed hearing loss, the conjoint occurrence of both auditory lesions, is also common. Conductive hearing loss results from granulomatous involvement of the middle-ear cavity, most often leading to serous otitis media. In contrast, the mechanism of inner-ear disease in WG is poorly understood. Granulomatous inflammation in the middle ear may compress the seventh cranial nerve (which courses through the middle-ear cavity), leading to a peripheral facial nerve palsy. Less commonly, vasculitic neuropathy infarcts the nerve at some point during its path through the temporal bone.

WG may be associated with several clinically important ocular lesions (Fig. 58.3). Retrobulbar masses, among the most treatment-refractory WG lesions, may lead to proptosis and visual loss through ischemia of the optic nerve. Scleritis, which causes eye pain and an angry, purplish scleral hue, may lead to scleromalacia perforans and visual loss (Chapter 73). Other ocular manifestations of WG include episcleritis, peripheral ulcerative keratitis, uveitis, conjunctivitis, nasolacrimal duct obstruction (characteristically leading to wet rather than dry eyes), and, occasionally, occlusion of the retinal arteries or veins.

Although the histological features of pulmonary WG are similar to those found in specimens from other tissues, the full pathologic spectrum may be more apparent in lung biopsy specimens (Fig. 58.4). Both vasculitic and necrotizing granulomatous features, which do not invariably coexist, may be confirmed in lung biopsy specimens. In addition to these two processes, pulmonary WG frequently demonstrates an extensive, nonspecific inflammatory background. The leukocytoclastic vasculitis in the lung may involve arteries, veins, and capillaries, with or without granulomatous features. Vascular necrosis begins as clusters of neutrophils within the blood vessel wall (microabscesses) that degenerate and become surrounded by palisading histiocytes. Coalescence of such neutrophilic microabscesses leads to extensive regions of 'geographic' necrosis. The range of granulomatous inflammation found in WG may include palisading granulomas, scattered giant cells, and poorly formed granulomas.

The clinical manifestations of pulmonary WG are equally diverse, ranging from asymptomatic lung nodules to fulminant alveolar hemorrhage. The most common radiographic findings are pulmonary infiltrates and nodules. The infiltrates, which may wax and wane, are often initially misdiagnosed as pneumonia. Nodules are usually multiple and bilateral, and often result in cavitation (Fig. 58.5). Hilar and/or mediastinal adenopathy is rare in WG, but has been reported.

Fig. 58.3 Ocular manifestations of Wegener's granulomatosis. (A) Bilateral retro-bulbar masses, causing proptosis of the left eye; (B) necrotizing scleritis.

Renal involvement is the most ominous clinical manifestation of WG. The typical lesion of WG (indeed, of all forms of AAV) is segmental necrotizing glomerulonephritis, usually associated with the formation of glomerular crescents (Chapter 67). The histopathology of renal disease in AAV – in contrast to mixed cryoglobulinemia and SLE, for example – is pauci-immune in nature (i.e., scant immunoglobulin or complement deposition). Thrombotic changes in the glomerular capillary loops are among the earliest histologic changes evident in AAV. Granulomatous changes, although frequently present, are identified only rarely in renal biopsies. The clinical presentation of renal disease in WG is that of rapidly progressive glomerulonephritis: hematuria, red blood cell casts, proteinuria (usually nonnephrotic), and progressive renal insufficiency. Without appropriate therapy, end-stage renal disease ensues within days to weeks. A commonly observed clinical occurrence is acceleration of the overall disease process once renal involvement is evident.

Less classic but nevertheless common features in WG are involvement of the musculoskeletal system, skin, and nervous system. Approximately half of all patients with WG are rheumatoid factor-positive, and RA is

Fig. 58.4 Histopathology of Wegener's granulomatosis. The pathologic features of Wegener's granulomatosis: (A) Langerhans giant cells and palisading granulomatous inflammation; (B) small-vessel vasculitis and fibrinoid necrosis of the lung; (C) 'geographic' necrosis.

a common misdiagnosis early in the disease course when nonspecific arthralgias and arthritis may occur. Migratory oligoarthritis and arthritis are a common presentation of disease flares. Unlike RA, the arthritis of WG tends to involve large joints and to spare the small joints of the hands. Splinter hemorrhages, digital ischemia, and digital gangrene resulting from inflammation in large digital arteries are underappreciated as manifestations of WG. Skin lesions in WG include the full panoply of lesions associated with cutaneous vasculitis (see section on hypersensitivity vasculitis, below). Although involvement of the brain parenchyma with WG has been reported, meningeal inflammation presenting as excruciating headaches and cranial neuropathies is a more common central nervous system manifestation of this disease. Finally, devastating mononeuritis multiplex may accompany WG, but this feature is less characteristic of WG than of the other major forms of AAV – MPA and CSS.

The clinical course of WG is marked by a tendency to recur following tapering or cessation of treatment. In one clinical trial, somewhat less than half of patients achieved disease remissions and maintained them

throughout the trial, which had a mean follow-up of approximately 2 years.²⁸ The requirement for repeated administration of the potentially toxic treatments in WG (discussed below) leads to substantial long-term morbidity.

MICROSCOPIC POLYANGIITIS

In 1948, Davson et al.²⁹ suggested the division of PAN patients into two groups based on the presence or absence of glomerulonephritis. One group of patients, Davson noted, demonstrated renal vasculitis only in medium-sized vessels of the kidneys (sparing the glomerulus). In contrast, patients in the other group had glomerular inflammation (i.e., small-vessel vasculitis, with or without medium-sized vessel involvement). This subset of patients with small-vessel vasculitis of the kidney was designated as having microscopic PAN. More recently, microscopic PAN has been renamed “microscopic polyangiitis,” in recognition of the tendency of MPA to involve not only arteries but also capillaries and veins as well.

The distinction of MPA from PAN was emphasized by the 1994 Chapel Hill Consensus Conference on the nomenclature of vasculitides,¹ which defined MPA as a process: (1) involving necrotizing vasculitis with few or no immune deposits; (2) affecting small blood vessels (capillaries, venules, or arterioles) as well as (perhaps) medium-sized arteries; and (3) demonstrating a tropism for the kidneys (glomerulonephritis) and lungs (pulmonary capillaritis). Microscopic polyangiitis (as opposed to polyarteritis) is the preferred term for this disorder, because the disease may affect arterioles, capillaries, venules, veins, and arteries in addition to arteries. Table 58.3 compares the principal features of MPA with those of classic PAN.

As with WG, a dominant feature of MPA is necrotizing glomerulonephritis with crescent formation (Fig. 58.6). In one study of 34 MPA patients with glomerulonephritis, the percentage of patients with functioning kidneys was only 55% and the actuarial survival only 65% at 5 years of follow-up, despite aggressive immunosuppressive therapies.³⁰ Pulmonary capillaritis, most typical of MPA, may rapidly lead to life-threatening hemorrhage from the lungs, requiring prompt, aggressive treatment (Fig. 58.7). In aggregate, the AAV constitute a far more common cause of this pulmonary renal syndrome than does anti-glomerular basement membrane (GBM) disease. In some cases, both ANCA and anti-GBM antibodies occur in the same patient, with disease outcomes generally worse than with either antibody alone.

Fig. 58.5 Chest computed tomography abnormalities in Wegener’s granulomatosis. Multiple, bilateral pulmonary nodules, several of which have cavitated.

Table 58.3 Features of microscopic polyangiitis versus classic polyarteritis nodosa

Feature	Microscopic polyangiitis	Classic polyarteritis nodosa
Granulomas	No	No
Vessel size	Small (and medium)	Medium
Renovascular hypertension	No	Yes
Rapidly progressive glomerulonephritis	Yes	No
Lung involvement	Alveolar hemorrhage	No
Mononeuritis multiplex	Yes	Yes
Anti-neutrophil cytoplasmic antibody (ANCA)-positive	P-ANCA (anti-myeloperoxidase)	Rare
Hepatitis B association	No	Sometimes (10%)
Vascular aneurysms	Occasionally	Commonly

In one series of MPA patients,³¹ renal manifestations (79%), weight loss (73%), mononeuritis multiplex (58%), and fever (55%) were the most common disease manifestations. Alveolar hemorrhage occurred in 12%. Upper respiratory tract symptoms in MPA are much milder than those associated with WG. MPA is not associated with erosion of the bony sinuses, scarring of the subglottic region, or saddle-nose deformities. The essential difference between MPA and WG, however, is the absence of granulomatous inflammation in MPA.

THE CHURG-STRAUSS SYNDROME

In 1951, Churg and Strauss reported a series of 13 patients with 'periarteritis nodosa' who demonstrated severe asthma and an unusual constellation of symptoms: 'fever . . . hypereosinophilia, symptoms of cardiac failure, renal damage, and peripheral neuropathy, resulting from vascular embarrassment in various systems of organs.'³² The investigators believed the syndrome to represent a new disease entity, which they termed 'allergic angiitis and allergic granulomatosis.' Three histologic criteria for this disorder, subsequently known as CSS, were specified: (1) presence of necrotizing vasculitis; (2) tissue infiltration by eosinophils (Fig. 58.8); and (3) extravascular granulomas. Today the diagnosis is often made on the basis of looser clinical criteria, because finding all three criteria in a single patient is challenging outside the autopsy room.

The 1990 American College of Rheumatology criteria for the classification of CSS³³ are intended to distinguish patients with CSS from those with other vasculitic disorders (Table 58.4). The presence of four or more of the six disease criteria yielded a sensitivity and specificity of 85% and 99.7% for CSS, respectively. The Chapel Hill Consensus Conference defined CSS as the presence of eosinophil-rich, granulomatous inflammation involving the respiratory tract, with necrotizing vasculitis of small to medium-sized vessels, associated with asthma and eosinophilia.¹ In addition to the other vasculitides, CSS must be distinguished from a group of hypereosinophilic disorders: Löffler syndrome, eosinophilic gastroenteritis, chronic eosinophilic pneumonia, the hypereosinophilic syndrome (HES), eosinophilic fasciitis, and eosinophilic leukemia.

Greater than 90% of CSS patients have histories of asthma. Typically the asthma is either of new onset or constitutes a significant exacerbation of long-standing disease. Upon encroachment of the vasculitis phase of CSS, patients' asthma may improve substantially, even before therapy for vasculitis is begun. Following successful treatment of the vasculitic phase, however, glucocorticoid-dependent asthma persists in many patients.

Chest radiographs are normal in the majority of CSS patients. Radiographic abnormalities are usually limited to fleeting pulmonary infiltrates, detected in one-third of patients. Pulmonary hemorrhage is unusual, and cavitary lesions should suggest the alternative diagnosis of WG. The pathological features of lung disease in CSS vary according to the disease phase: in the prodromal phase, there is extensive eosinophilic

Fig. 58.7 Alveolar hemorrhage in microscopic polyangiitis.

Fig. 58.8 Eosinophilic infiltration of a salivary gland.

infiltration of the alveoli and interstitium; during the vasculitic phase, necrotizing vasculitis and granulomas are evident. Upper-airway disease in CSS usually takes the form of nasal polyps or allergic rhinitis. A high percentage of patients have histories of nasal polypectomies, often long before the diagnosis is considered. Although pansinusitis occurs frequently, destructive upper-airway disease is not characteristic of CSS.

In contrast to WG, mononeuritis multiplex occurs with a remarkable frequency in CSS. This potentially disabling complication was evident in 74 of the 96 patients (77%) in one series.³⁴ Cardiac involvement (usually congestive heart failure) also occurs with a disproportionate frequency in CSS; cardiac complications are a common mode of death in CSS. Renal disease in CSS has been described as less common and less malignant compared to that associated with other AAV. When it occurs, histopathological findings are often indistinguishable from those of WG, MPA, and other forms of pauci-immune glomerulonephritis, with the possible exception of increased eosinophils in CSS biopsies.

Peripheral blood eosinophilia is a hallmark of CSS, with eosinophils accounting for up to 60% of the white blood cell count (before treatment). Approximately 50% of CSS patients test positive for ANCA, which is usually directed to MPO.

CLINICAL PEARLS

THREE PHASES OF THE CHURG-STRAUSS SYNDROME (CSS)

- >> Prodromal phase, characterized by the presence of allergic disease (typically asthma or allergic rhinitis), which may last from months to many years
- >> Eosinophilia/tissue infiltration phase, in which remarkably high peripheral eosinophilia may occur and tissue infiltration by eosinophils is observed in the lung, gastrointestinal tract, and other tissues
- >> Vasculitic phase, in which systemic necrotizing vasculitis afflicts a wide range of organs, ranging from the heart and lungs to peripheral nerves and skin

Although clinical remissions may be obtained in more than 90% of patients with CSS, disease recurrences are common upon cessation of therapy (as with other AAVs). In the largest series reported to date, flares were detected in more than 25% of the patients.³⁴ In most cases, relapses were heralded by the return of eosinophilia. Many patients develop steroid-dependent asthma after the vasculitic phase of their disease appears to have subsided. Distinguishing simple asthma flares from CSS recurrences can be challenging in such cases.

TREATMENT OF THE ANCA-ASSOCIATED VASCULITIDES

Patients with WG, MPA, or CSS whose symptoms constitute immediate threats to either the function of vital organs or to the patient's life urgently require treatment with both a cytotoxic agent (usually cyclophosphamide) and high doses of glucocorticoids. The current standard of care for patients with severe disease of this nature is cyclophosphamide for 3–6 months, followed by azathioprine for an additional 18 months.^{35, 36} Limited forms of WG may respond to the combination of glucocorticoids and methotrexate, thus sparing patients the potential side effects of cyclophosphamide. Increasing experience with methotrexate and prednisone has demonstrated, however, that durable remissions of WG with this regimen are rare, and smoldering or recurrent disease that reactivates upon taper of the medications is the rule. A substantial number of patients with CSS achieve satisfactory responses with glucocorticoids alone, and monotherapy is a reasonable first approach for many of these patients. However, patients with evidence of rapidly progressive glomerulonephritis or symptoms of mononeuritis multiplex should be treated promptly with both cyclophosphamide and glucocorticoids to halt these devastating disease manifestations.

Practice regarding the use of either daily or intermittent (e.g., monthly intravenous) cyclophosphamide varies from center to center. Remission is induced with either daily or intermittent regimens of cyclophosphamide (combined with glucocorticoids) in high percentages of patients. Regardless of the route by which cyclophosphamide is administered, however, the medication is associated with potential hazards. Careful monitoring, particularly of the white cell count, is essential. Complete blood counts every 2 weeks are advised for patients on cyclophosphamide. The induction of

Table 58.4 American College of Rheumatology classification criteria for Churg–Strauss syndrome

Criterion	Definition
Asthma	History of wheezing or diffuse high-pitched rales on expiration
Eosinophilia	Eosinophilia > 10% on white blood cell differential count
Mononeuropathy or polyneuropathy	Development of mononeuropathy, multiple mononeuropathies, or polyneuropathy (i.e., stocking/glove distribution)
Pulmonary infiltrates, nonfixed	Migratory or transitory pulmonary infiltrates on radiographs
Paranasal sinus abnormality	History of acute or chronic paranasal sinus pain or tenderness, or radiographic opacification of the paranasal sinuses
Extravascular eosinophils	Biopsy including artery, arteriole, or venule, showing accumulations of eosinophils in extravascular areas

(From Masi A, Hunder G, Lie J, et al. The American College of Rheumatology 1990 criteria for the classification of Churg–Strauss syndrome (allergic granulomatosis and angiitis). *Arthritis Rheum* 1990; 33: 1094.)

THERAPEUTIC PRINCIPLES

TREATMENT OF ANTI-NEUTROPHIL CYTOPLASMIC ANTIBODIES (ANCA)-ASSOCIATED VASCULITIDES

- >> The presence of symptoms that constitute immediate threats to either function of vital organs or to survival requires urgent treatment with both a cytotoxic agent and high doses of glucocorticoids
- >> In patients with severe disease, cyclophosphamide is the cytotoxic drug of choice
- >> Limited forms of Wegener's granulomatosis may respond to a combination of glucocorticoids and methotrexate, but durable remissions with this regimen are rare
- >> In Churg–Strauss syndrome patients without serious organ involvement, treatment with glucocorticoids is a reasonable first approach. However, the presence of glomerulonephritis or mononeuritis multiplex requires immediate treatment with cyclophosphamide and glucocorticoids

neutropenia is not required to achieve a therapeutic effect in AAV, and avoidance of this side effect is highly desirable as a strategy to prevent opportunistic infections. Cyclophosphamide should be temporarily withheld if the WBC count falls below $4.0 \times 10^6/\mu\text{l}$. The multitude of side effects associated with long-term use of cyclophosphamide has inspired the use of shorter courses of induction treatment (e.g., 3–6 months), followed by longer-term maintenance of remission with either azathioprine or methotrexate. A wide array of other therapies, e.g., plasmapheresis or intravenous immunoglobulin, has been employed in small numbers of patients, but insufficient data exist to judge their efficacy. The use of IFN- α in the treatment of CSS appears promising,³⁷ but larger studies are required.

Results of a recent trial of etanercept (a soluble TNF inhibitor) added to standard therapy for remission maintenance were instructive.²⁸ Although at least temporary disease control was achieved in a high proportion of patients – 87% in the etanercept group, 91% in the control group – this disease control was due to the conventional therapies that patients in both treatment arms received. Disease flares were common in both groups, with a total of 118 in the etanercept group (23 severe, 95 limited) and 134 in the control group (25 severe, 109 limited). With regard to the trial's primary outcome, sustained remission, the percentages of patients who achieved this measure were not different: 70% in the etanercept group, 75% in the control group. Most strikingly, in the WGET cohort overall, only 49% of patients achieved disease remissions and maintained them throughout the trial. In the two groups combined, 57% of the patients suffered at least one severe or life-threatening adverse event (no difference between groups). Most adverse effects, with the possible exception of solid malignancies,³⁸ were attributable to conventional therapies rather than to etanercept. There were 6 deaths, but none from overwhelming WG.

Two other randomized trials in ANCA-associated vasculitis^{35,39} confirm the high likelihood of controlling the disease with conventional therapies but also the high likelihood of disease flares once these therapies are tapered. Particularly critical in the maintenance of remission appears to be some dose of maintenance glucocorticoid.⁴⁰

POLYARTERITIS NODOSA

PAN, the grandfather of all the vasculitides, was described in 1866 by Kussmaul and Maier.⁴¹ The patient was a 27-year-old journeyman tailor who died from a multisystem illness characterized by fever, weight loss, polyneuropathy, and abdominal pain. The nodular swellings found along the course of muscular arteries at autopsy prompted Kussmaul and Maier to term the disease 'periarteritis nodosa.' The term was unfortunate because in fact the inflammatory process consists of a panarteritis that involves the entire thickness of the vessel wall. Subsequent authors have adopted the more accurate name 'polyarteritis nodosa.'

PAN can begin in childhood or in the eighth decade of life, but the average age of onset is about 40–45 years. Series vary in the proportion of men and women afflicted. Some 10–30% of patients develop the disease related to infection with hepatitis B, due to the deposition of ICs containing viral antigens.⁴² In the remainder of cases, the etiology remains unknown. No genetic susceptibility to PAN has been identified, and familial PAN is exceedingly rare.

CLINICAL FEATURES

The initial symptoms of PAN are usually nonspecific, such as malaise, fatigue, fever, and extremity pain from myalgia or arthralgia (Table 58.5). Typically, it is not until weeks or months later that patients develop signs of vasculitis. The most helpful clinical clues often come from the skin and peripheral nerves because these areas are affected relatively early, and their manifestations of vasculitis are distinctive. Skin lesions of PAN include livedo reticularis, subcutaneous nodules, leg ulcers, palpable purpura, and digital gangrene.⁴³

Mononeuritis multiplex, a peripheral neuropathy characterized by the segmental infarction of named nerves, is both one of the most specific clues to vasculitis and a hallmark of PAN. Mononeuritis multiplex most often affects the peroneal, tibial, ulnar, median, and radial nerves, leading to foot or hand symptoms (e.g., foot or wrist drop). Mononeuritis multiplex almost always causes sensory abnormalities, particularly painful dysesthesias. Motor involvement occurs in one-third of patients. Sometimes patients with PAN appear to have a (nonspecific) symmetrical polyneuropathy. In such cases, electrodiagnostic testing may unmask greater asymmetry to the process than is evident clinically, and also confirm that the pattern of nerve injury is one of axonal degeneration.

The gastrointestinal tract is also frequently involved in PAN.⁴⁴ The classic manifestation is 'intestinal angina' – periumbilical pain starting 30–60 minutes after eating. The pain results from intestinal ischemia occurring because the increased metabolic demands of the bowel after eating cannot be met by the limited blood flow in inflamed mesenteric vessels. Ischemic bowel can be difficult to recognize, especially in patients receiving glucocorticoids, which blunt the signs of acute abdomens. Vasculitis of individual organs can mimic cholecystitis and appendicitis.

Renal involvement is nearly universal at autopsy in PAN, but tends to produce few clinical symptoms. The new onset of hypertension, hematuria, and rising serum creatinine are the most common signs. Renin-mediated hypertension, a hallmark of PAN, is rare in ANCA-associated vasculitis, which tends to involve smaller vessels and glomeruli rather than medium-sized interlobar renal arteries.

Cardiac involvement, often striking at autopsy, is usually inconspicuous during life. Pericardial effusions, cardiomyopathy, and myocardial infarctions are the most common manifestations. Central nervous system

Table 58.5 Clinical features in patients with polyarteritis nodosa

Clinical feature	Percentage with finding
General	
Fever	71

(From Cupps T, Fauci A. Systemic necrotizing vasculitis of the polyarteritis nodosa group. In: Smith LH (ed) *The Vasculitides. Major Problems in Internal Medicine*, vol. 21. Philadelphia: WB Saunders; 1981:26.)

disease usually results from hypertension rather than intracranial vasculitis, but involvement of cerebral blood vessels sometimes occurs. Scleritis is the most common ocular manifestation. Testicular infarction can occur early in the course, causing acute pain and swelling that mimics torsion of the testicle. Remarkably, as noted by Kussmaul and Maier, PAN spares the lung parenchyma.

Although PAN typically involves multiple organs, limited forms have been described. Cutaneous PAN is a medium-vessel vasculitis limited to the skin, causing nodules or ulcers. Over time, some of these patients develop systemic disease. Some cases of cutaneous PAN are induced by drugs (especially minocycline and propylthiouracil) and are associated with ANCA.

The laboratory features of PAN, though frequently strikingly abnormal, are nonspecific. Anemia, mild thrombocytosis (except in perforation of the gut, which is associated with thrombocytopenia), elevation of the erythrocyte sedimentation rate (ESR), and microscopic hematuria are common.

The pathologic changes in PAN involve small and medium-sized arteries and may be macroscopic and microscopic. Involved arteries may show readily visible aneurysmal bulges of the vessel wall. Infarctions, ruptured aneurysms, and gangrenous tissue may be easily visible. Histological sections show inflammatory cells infiltrating the vessel wall (Fig. 58.9), leading to fibrinoid necrosis. Varying degrees of intimal proliferation and thrombosis occur. Lesions tend to be segmental and to favor branch points. In the acute phase of the illness, the inflammatory infiltrate consists chiefly of neutrophils, whereas mononuclear cells predominate in the chronic phase. Granulomas are absent in PAN, and eosinophils are rarely prominent.

DIAGNOSIS

Criteria for the classification of PAN have been developed by the American College of Rheumatology (ACR) (Table 58.6).⁴⁵ Diagnostic certainty requires a positive biopsy or an angiogram demonstrating characteristic microaneurysms (Fig. 58.10). Biopsies of symptomatic sites such as nerve, muscle, or testicle are often useful (sensitivity, 60–70%; specificity ~97%). In the absence of a symptomatic site to biopsy, mesenteric angiography may demonstrate telltale microaneurysms (sensitivity ~60%; specificity, 99%).

TREATMENT AND PROGNOSIS

For patients with idiopathic PAN, treatment usually consists of prednisone and cyclophosphamide. In the precorticosteroid era, only 13% of patients survived 5 years. With high doses of glucocorticoids, it is estimated that approximately half of all patients can achieve remission with prednisone alone. Although there have been few controlled trials (and even case series of PAN are contaminated by patients with other diagnoses, such as MPA or CSS), the only randomized controlled trial comparing prednisone alone with prednisone and cyclophosphamide showed no difference in 10-year survival – approximately 70% in both treatment groups.⁴⁶ Patients treated with cyclophosphamide, however, experienced fewer relapses than those treated with prednisone alone (9% versus 38% of patients). Thus, for severe PAN or for cases that are refractory to initial therapy with prednisone, the combination of glucocorticoids and cyclophosphamide is the standard of care. When using cyclophosphamide to treat PAN, achieving leukopenia is neither required nor desirable. Indeed, frequent monitoring of the white blood cell count (e.g., every 2 weeks) is advisable so that leukopenia can be detected early and cyclophosphamide reduced or stopped as needed. The relative efficacy of daily versus intermittent (e.g., monthly) cyclophosphamide is not clear.

Most patients begin to improve within 2–4 weeks of starting treatment. Tapering of prednisone may begin after the first month and is slowly continued until the drug is stopped after 6–12 months. Whenever possible, cyclophosphamide should be discontinued after 6 months and replaced by a less toxic medication (e.g., azathioprine) for the completion of one full year of therapy.

Antiviral agents have revolutionized the treatment of PAN associated with hepatitis B. Before the availability of antiviral agents, all survivors of PAN treated with immunosuppression alone became chronic carriers of hepatitis B and assumed the risks of cirrhosis and hepatoma. The availability of antiviral agents permitted a treatment strategy based on an understanding of disease pathogenesis.⁴⁷ Initially patients are treated with prednisone (1 mg/kg per day) to suppress the inflammation. After the first week, prednisone is rapidly tapered and then discontinued over 3–7 days, and antiviral therapy (e.g., lamivudine 100 mg/day or entecavir

Fig. 58.9 Polyarteritis nodosa histopathology. Photomicrographs of a jejunal specimen obtained at laparotomy from a 74-year-old man who died of complications of mesenteric ischemia related to polyarteritis nodosa. **(A)** Viable-appearing jejunal mucosa with the loss of villi is seen in the lower left corner of the photomicrograph. In the remainder of the visible lumen, the mucosa is replaced by a highly inflamed, ischemia-induced ulcer. In the lower right corner, there is a narrowed, chronically inflamed, medium-sized artery (arrow) surrounded by a lymphocytic infiltrate. **(B)** Higher-powered view of the artery shown in Figure 58.9A (arrow), along with several other inflamed arteries. The extensive lymphocytic infiltrate indicates the chronic nature of the inflammatory process. **(C)** Elastin stain of an artery (ART) and a vein (V) within the wall of the jejunum. The internal elastic lamina of the artery has been disrupted focally by the inflammatory process, and fibrinoid necrosis is present. **(D)** Medium-sized muscular artery from the jejunum, characterized by chronic lymphocytic inflammation, abundant fibrinoid necrosis (FN), and luminal narrowing. (Reproduced with permission from Levine SM, Hellmann DB, Stone JH. Gastrointestinal involvement in polyarteritis nodosa (1986–2000): presentation and outcomes in 24 patients. *Am J Med* 2002; 112: 386.)

0.5 mg/day) is started. For several weeks throughout this period, plasma exchange is carried out 2–3 times a week for an average of about 20 exchanges per patient, depending on clinical response. With this regimen, 80% of patients survive the vasculitis and 56% no longer demonstrate serologic evidence of hepatitis B replication.

Treatment for PAN associated with hepatitis C

The treatment of hepatitis C-associated PAN is discussed in the section on cryoglobulinemia.

MIXED CRYOGLOBULINEMIA

Wintrobe discovered cryoglobulins in 1931 when, in the course of evaluating a 56-year-old woman with anemia, Raynaud's phenomenon, and symptoms of hyperviscosity – she ultimately turned out to have myeloma – he refrigerated a tube of the patient's blood and noted the formation of a precipitate in her plasma.⁴⁸ To share his discovery with colleagues, he placed the tube in his coat pocket and walked to the wards. Pulling the tube from his warm pocket he was startled to see that his discovery had vanished. This experience helped to define the

Table 58.6 Criteria for classification of polyarteritis nodosa

1. Weight loss ≥ 4 kg
2. Livedo reticularis
3. Testicular pain or tenderness
4. Myalgias, weakness, or leg tenderness
5. Mononeuropathy or polyneuropathy
6. Diastolic blood pressure > 90 mmHg
7. Elevated blood urea nitrogen or creatinine
8. Hepatitis B virus
9. Arteriographic abnormalities
10. Biopsy of small or medium-sized artery containing polymorphonuclear cells in the vessel wall

For classification purposes, a patient shall be said to have polyarteritis nodosa if at least three of these 10 criteria are present (From Lightfoot R, Michel B, Bloch D, et al. The American College of Rheumatology 1990 criteria for the classification of polyarteritis nodosa. *Arthritis Rheum* 1990; 33: 1088.)

hallmark of cryoglobulins – antibodies that precipitate under conditions of cold and solubilize on rewarming (see below).⁴⁹

Cryoglobulins are classified into three types (I, II, or III) (Table 58.7) based on whether or not they are monoclonal, and demonstrate rheumatoid factor activity.^{50, 51} Type I cryoglobulins, characteristically found in hematopoietic malignancies, are monoclonal but do not have rheumatoid factor activity. Cryoglobulin types II and III, which typically occur in autoimmune disorders and infections, are designated mixed cryoglobulins, because they consist of both IgG and IgM. The IgM component in type II and type III cryoglobulinemia has rheumatoid factor activity. In type II cryoglobulinemia, the IgM is monoclonal, whereas in type III it is polyclonal. Not all patients with cryoglobulins have symptoms. Indeed, half of all patients with hepatitis C have demonstrable cryoglobulins, yet vasculitis occurs in $< 1\%$. Vasculitis results when ICs containing cryoglobulins and antigenic components deposit in blood vessel walls and activate complement.

The clinical syndrome and underlying disease can be predicted from the type of cryoglobulin present. For example, monoclonal cryoglobulins without rheumatoid factor activity (type I) do not activate complement effectively and are more likely, as in Wintrobe's patient, to cause hyperviscosity than vasculitis. In contrast, the mixed cryoglobulinemias (types II and III) often activate complement efficiently, and are prone to cause vasculitis.

After the discovery of hepatitis C virus (HCV), it quickly became evident that this infection accounted for more than 80% of the cases of 'essential' mixed cryoglobulinemia (EMC). The precise mechanism by which HCV and other infections induce cryoglobulins and the syndrome of EMC is not clear.

Among patients with HCV and mixed cryoglobulinemia, approximately one-third have type II cryoglobulins and two-thirds have type III. Type II mixed cryoglobulinemia developed a mean of 7.6 years after infection, and type III mixed cryoglobulinemia after a mean of 13.7 years following infection.⁵² The genetic susceptibility of individual patients to EMC, the duration of HCV infection, and the genotype of particular HCV subspecies may explain why only some patients with HCV develop EMC.

Fig. 58.10 Angiograms in polyarteritis nodosa. **(A)** Large aneurysms in the distribution of the splenic artery in a 60-year-old woman with polyarteritis nodosa. The largest of these aneurysms ruptured, requiring an emergent laparotomy. **(B)** Multiple microaneurysms within the renal parenchyma in a 24-year-old man with polyarteritis nodosa. Table 58.7 Classification of cryoglobulins and their immunochemical features and clinical associations

Type	Rheumatoid factor activity	Monoclonal association	Clinical syndrome	Disease present
I	Yes (usually IgG)	No	Hyperviscosity	Malignancy
II	Yes (IgM)	Yes	Vasculitis	Hepatitis C Rheumatic diseases Malignancy Idiopathic
III	No	Yes	Vasculitis	Hepatitis C Rheumatic diseases Idiopathic

Ig, immunoglobulin.

Mixed cryoglobulinemia causes small-vessel vasculitis with a predilection for the skin, peripheral nerves, and kidney. The most common manifestation is recurrent crops of palpable purpura on the legs (Fig. 58.11). Other common manifestations are dysesthesias and mononeuritis multiplex caused by vasculitic neuropathy, glomerulonephritis, arthralgias, malaise, and fatigue. Some patients develop mesenteric vasculitis, Raynaud's phenomenon, livedo reticularis, or secondary Sjögren's syndrome. Lung and heart disease are uncommon. Some patients with mixed cryoglobulinemia develop a severe medium-vessel vasculitis with large, painful ulcerations that are clinically indistinguishable from those of PAN.

Most patients with mixed cryoglobulinemia have anemia, an elevated ESR, and elevated liver transaminases. Those with type II mixed cryoglobulinemia usually show an IgM- γ monoclonal spike. Ninety percent of patients with mixed cryoglobulinemia vasculitis are hypocomplementemic, with C4 levels characteristically more depressed than C3. Biopsies of petechial lesions in the skin or gastrointestinal tract show leukocytoclastic vasculitis, with IF studies revealing IgG and IgM deposition in both medium and small blood vessels. Renal biopsies in patients with type II mixed cryoglobulinemia typically show membranoproliferative glomerulonephritis (Chapter 67). The diagnosis of cryoglobulinemic vasculitis is established by isolating type II or type III cryoglobulins following refrigeration at 4°C for several days and by demonstrating vasculitis pathologically (usually by skin biopsy).

The treatment of mixed cryoglobulinemia is often challenging. For patients with mild symptoms such as infrequent crops of purpura, no therapy is required. For those with HCV-associated mixed cryoglobulinemia, frequent purpura, and a mild vasculitic neuropathy, pegylated IFN (1.5 μ g/kg per week) and ribavirin (1000–1200 mg/day) may be effective.⁵³ Fewer than half of patients with HCV-associated mixed cryoglobulinemia respond to antiviral therapy. Patients younger than 60 who do not have HCV genotype 1 (the most common in Americans) are more likely to respond. This regimen eliminates purpura, reduces the cryocrit, normalizes complement levels, and eliminates HCV-RNA in 30–60% of patients. Unfortunately, up to 90% of patients relapse (clinically or serologically) if the therapy is discontinued. For this reason, antiviral therapy is sometimes continued indefinitely (albeit at lower doses). For those with life-threatening vasculitides, high-dose prednisone, cyclophosphamide (in doses identical to those used in

**Fig. 58.11** Purpura in vasculitis. Palpable purpura in a patient with cryoglobulinemic vasculitis.

PAN), and plasmapheresis are recommended. If the vasculitis improves and the immunosuppression can be tapered, then antiviral therapy is added.

HYPERSENSITIVITY VASCULITIS

The proliferation of names for cutaneous vasculitis is principally due to the fact that, compared to the relatively limited number of disorders that cause large- or medium-vessel arteritis, a host of disorders can be associated with small-vessel vasculitis of the skin. These disorders include both primary vasculitides and secondary causes of vasculitic inflammation. Whereas some of these conditions cause only cutaneous vasculitis, others can also cause organ- or life-threatening involvement of vital organs, such as the lungs or kidney. This section focuses on types of small-vessel

vasculitis confined to the skin. Other prominent causes of cutaneous vasculitis, e.g., cryoglobulinemia, HSP, urticarial vasculitis, the ANCA-associated disorders, and cutaneous PAN, are discussed separately in other sections of this chapter.

In 1952, in the first classification scheme ever devised for the vasculitides, Zeek⁵⁴ coined the term ‘hypersensitivity vasculitis.’ The purpose of this term was to distinguish a form of necrotizing arteritis that involved only small blood vessels from PAN, which has a predilection for larger vessels. The word ‘hypersensitivity’ stemmed from animal models of vasculitis induced by the administration of horse serum, sulfonamides, and other drugs. These vasculitis models – attempts to develop an animal model of PAN – differed from PAN in their prominent cutaneous involvement, their involvement of the venous as well as the arterial circulation, and their involvement of small blood vessels, i.e., arterioles, venules, and capillaries. Moreover, in contrast to PAN, all of the lesions in hypersensitivity vasculitis tended to occur in “crops,” and thus were approximately the same age. Finally, in contrast to the characteristically unrelenting nature of PAN, hypersensitivity vasculitis was self-limited.

Since Zeek’s first description of hypersensitivity vasculitis, the term has been narrowed to denote small-vessel vasculitis confined principally to the skin and not associated with any other primary vasculitis (e.g., HSP, WG, or cryoglobulinemia). The identification of an inciting antigen for the vasculitis is not a prerequisite to the diagnosis, because no such provocation is found in many patients who fit the clinical and pathological picture of the disease.

The ACR-formulated criteria for the classification of hypersensitivity vasculitis included: (1) age of onset greater than 16 years; (2) medication at disease onset; (3) palpable purpura; (4) maculopapular rash; and (5) biopsy of arteriole or venule showing granulocytes in a perivascular or extravascular location.⁵⁵ The presence of three of five criteria resulted in sensitivity of 71% and specificity of 84%.

The 1994 Chapel Hill Consensus Conference on nomenclature of the vasculitides proposed an alternative term for hypersensitivity vasculitis – cutaneous leukocytoclastic angiitis – because of the frequent failure to identify a precipitant (no manifest cause of hypersensitivity). This designation is also problematic, however, because although most lesional skin biopsies demonstrate a neutrophil predominance, others show a

primarily lymphocytic infiltration. Moreover, these two histopathological patterns do not appear to represent different evolutionary stages of the same process, but rather (at a minimum) two distinct processes, underscoring the difficulty of using a single term to define all patients with this clinical phenotype.

Regardless of the name, certain similarities exist among patients who present with symptoms and signs of cutaneous vasculitis. First, the lesions typically occur first in dependent regions, i.e., the lower extremities or buttocks. Second, the lesions may be asymptomatic, but are usually accompanied by a burning or tingling sensation. A wide array of skin lesions may occur, including palpable purpura, papules, urticaria/angioedema, erythema multiforme, vesicles, pustules, ulcers, and necrosis. The simultaneous occurrence of livedo reticularis usually indicates the involvement of medium-sized arteries as well. Most cases with a clearly identified precipitant resolve over a period of 1–4 weeks, often with some residual hyperpigmentation or, in the case of ulcerated lesions, scars. A subset of patients, however, have recurrent disease that remains confined to the skin and requires prolonged therapy.

The pleomorphic lesions of cutaneous vasculitis and the large number of mimics of vasculitis make confirmation of the diagnosis by skin biopsy essential. Biopsy of an active lesion (<48 hours old, if possible) usually demonstrates leukocytoclastic vasculitis of the postcapillary venules (Fig. 58.12). IF shows variable quantities of immunoglobulin and complement deposition, confirming the importance of ICs to the underlying disease process but not demonstrating a diagnostic pattern. The performance of IF studies, however, is an important (and often neglected) part of the workup, critical for the exclusion of HSP, urticarial vasculitis, and cryoglobulinemia. The workup for a patient with possible HSV includes a number of other laboratory studies to exclude internal organ involvement and to differentiate from other diseases (Table 58.8).

Treatment strategies for hypersensitivity vasculitis are largely empiric. The type, intensity, and duration of therapy are based on the degree of disease severity in an individual patient. For cases in which a precipitant can be identified, removal of the offending agent usually leads to resolution of hypersensitivity vasculitis within days to weeks. Mild cases may be treated simply with leg elevation and the administration of nonsteroidal anti-inflammatory drugs (and/or H₁ antihistamines). Colchicine,

hydroxychloroquine, or dapsone may be tried for persistent disease that does not lead to cutaneous gangrene. For refractory or more severe disease, immunosuppressive agents may be indicated, generally beginning with glucocorticoids. Failure of the patient to tolerate a steroid taper over some weeks or the requirement for excessive glucocorticoids dictates the use of an additional immunosuppressive agent. Azathioprine is commonly used for this purpose.

HENOCCH-SCHÖNLEIN PURPURA

HSP is a distinct form of small-vessel vasculitis characterized by nonthrombocytopenic purpura, arthritis, abdominal pain, and renal disease.^{56, 57} The histopathologic findings are those of a leukocytoclastic vasculitis with IgA deposition. HSP can develop at any age, but occurs most frequently in children. Indeed, HSP is the most common form of vasculitis in children. The mean age of children with HSP is 5.9 years, and 93% of affected children are less than 9 years old. The disease often remits spontaneously but sometimes causes life-threatening or chronic complications, most notably gastrointestinal hemorrhage (especially in children) and nephritis (especially in adults). Although the cause is unknown, an infectious trigger is suggested by the fact that two-thirds of patients experience an acute, virus-like, upper respiratory illness an average of 10 days before the onset of HSP, and by the seasonal variation of the disease (cases are more likely in the fall and winter months). The central role of IgA in the pathogenesis of HSP is emphasized by the demonstration that most patients have increased serum IgA levels, IgA-containing circulating ICs, and IgA deposition in inflamed blood vessels.

• Duodenal obstructions	1
Recurrence of symptoms	33

(From Saulsbury F. Henoch-Schönlein purpura in children. *Medicine* 1999; 78: 395.)

Typically, patients present with acute onset of fever, palpable purpura on the lower extremities and buttocks, abdominal pain, arthritis, and hematuria (Table 58.9). The purpura tends to be extensive, producing lesions too numerous to count. Although the purpura is most extensive on the legs and buttocks, it can involve the arms and, infrequently, the trunk. In some patients, the cutaneous involvement takes the form of maculopapular lesions, blisters, and ulcers. The abdominal pain is often colicky and may worsen after eating (i.e., intestinal angina). Some patients experience nausea, vomiting, and upper or lower gastrointestinal bleeding. Joint disease manifests as arthralgias or arthritis in large joints, especially the knees and ankles, and to a lesser degree, the wrists and elbows. Migratory patterns can be seen.

The clinical hallmark of nephritis in HSP is hematuria, which is usually microscopic. Proteinuria almost never occurs in the absence of hematuria. Unlike gastrointestinal disease and arthritis, which occasionally precede the onset of purpura, nephritis almost always follows the appearance of skin disease. Other organs are rarely involved, but pulmonary involvement can be manifested by hemoptysis, and central nervous system involvement can result in subarachnoid or intracerebral bleeding. With the exception of renal disease, HSP is self-limited, lasting an average of 4 weeks (range, 3 days–2 years).

The manifestations of HSP vary with age. Among children with HSP, infants have milder disease. Children under the age of 2 are less likely than older children to develop nephritis or abdominal complications. As a group, children differ from adults with HSP in having more frequent gastrointestinal symptoms and less frequent renal disease. Gastrointestinal involvement in children can cause intussusception, which rarely occurs in adults. Renal disease, which affects 50–85% of adult HSP patients, is also more likely to lead to renal insufficiency compared to children.

Routine blood tests show few abnormalities other than a mild leukocytosis. The ESR is elevated in only about a third of patients. Urinalysis reveals hematuria, proteinuria, and red cell casts, but the serum creatinine is usually normal. Approximately 60% of patients have an elevated serum IgA. Although there are two subclasses of IgA, HSP is associated with increases only in IgA₁.⁵⁷ Serum complement levels are usually normal.

Leukocytoclastic vasculitis is the dominant finding in most affected organs, including the skin and gut. Deposition of IgA can be demonstrated in most lesional skin biopsies. Renal lesions range from minimal-change disease to focal or diffuse proliferative glomerulonephritis with crescents. IF studies characteristically demonstrate IgA deposition in the mesangium.

Classification criteria for HSP have been established by the ACR to help differentiate this disease from other vasculitides.⁵⁸ The differential diagnosis of HSP includes other disorders that cause leukocytoclastic vasculitis. Cryoglobulinemia shares the predilection of HSP for producing purpura, hematuria, and abdominal pain. Cryoglobulinemia is more likely than HSP to recur chronically. Tests for cryoglobulin and HCV help to distinguish the two conditions, and the finding of IgA deposition within lesional biopsies strongly favors HSP. Hypersensitivity vasculitis, unlike HSP, should not be associated with hematuria or gastrointestinal complaints. Unlike AAV, which can also produce purpura, hematuria, and arthritis, HSP seldom affects the lungs. Patients with AAV also differ from those with HSP in that the ANCA associated with those diseases are typically IgG and the glomerulonephritis is pauci-immune, not associated with substantial IgA deposition. Infrequently, bacterial endocarditis and other infections can produce purpura and hematuria that resemble HSP. The purpuric lesions associated with thrombocytopenia are usually extremely fine, very small (albeit diffuse), and not palpable.

Treatment of HSP has not been studied extensively. Most patients, especially children, have a self-limited disease course. Nonsteroidal anti-inflammatory drugs may alleviate arthralgias but can aggravate gastrointestinal symptoms and should be avoided in any patient with renal disease. Although glucocorticoids have not been evaluated rigorously in HSP, they appear to ameliorate joint and gastrointestinal symptoms. Glucocorticoids do not appear to improve the rash, however, and their effectiveness in renal disease is controversial.⁵⁷ Uncontrolled trials suggest that high-dose methylprednisolone followed by oral prednisone or high-dose prednisone combined with azathioprine or cyclophosphamide may help patients with severe nephritis (i.e., nephrotic syndrome and > 50% crescents). Chronic renal failure is rare except in adults with more than 50% crescents on renal biopsy.

■ BEHÇET'S DISEASE ■

The triad of recurrent mouth ulcers, genital ulcers, and eye inflammation was first recognized as a distinct syndrome in 1937 by the Turkish dermatologist, Dr Hulusi Behçet.⁵⁹ In addition to these manifestations, Behçet's disease can affect nonmucosal surfaces of skin, the central nervous system, the gastrointestinal tract, and other organs. Most of the tissue damage in Behçet's disease results from vasculitis. Although Behçet's disease most commonly affects small and medium arteries, it can involve larger arteries and has a proclivity – in contrast to PAN, for example – to involve veins as well as arteries. The cause is unknown. Most patients are in their 20s or 30s at disease onset. Behçet's disease is rare in North America, where it affects only 1 out of 500 000 people, but is 100 times more common along the ancient Silk Route, which includes Greece, Turkey, Saudi Arabia, Iran, Korea, China, and Japan. Genetic factors also affect susceptibility to the disease, especially in Asia, where up to 80% of patients have the human leukocyte antigen (HLA)-B51 allele.

The diagnosis of Behçet's disease rests upon a set of established criteria (Table 58.10). No single clinical or laboratory feature is pathognomonic, but the diagnosis is untenable in the absence of recurrent aphthous ulcers

of the mouth (Fig. 58.13). The mouth ulcers usually number 2–10 and can affect the tongue, buccal mucosa, gums, and pharynx. The oral ulcers can cause such severe odynophagia that some patients lose weight and become dehydrated. Most patients also experience intermittent painful genital ulcers. Ocular disease, which most commonly presents as anterior or posterior uveitis, can cause substantial disability in Behçet's disease. The anterior uveitis, typically associated with a red, photophobic eye, may be so intense that pus in the anterior chamber produces a white meniscus, called a hypopyon, evident on examination. Scar tissue or synechiae formation between the iris and the lens can lead to distortion of the pupil. With posterior uveitis, essentially a retinal vasculitis, lesions may be

Fig. 58.13 Aphthous oral ulcers in a patient with Behçet's disease.

Table 58.10 Criteria for the diagnosis of Behçet's disease

Finding	Definition
Recurrent oral ulceration	Minor aphthous, major aphthous, or herpetiform ulcers observed by the physician or patient, which have recurred at least three times over a 12-month period
Recurrent genital ulceration	Aphthous ulceration or scarring observed by the physician or patient
Eye lesions	Anterior uveitis, posterior uveitis, or cells in the vitreous on slit-lamp examination; or retinal vasculitis detected by an ophthalmologist
Skin lesions	Erythema nodosum observed by the physician or patient, pseudofolliculitis, or papulopustular lesions, or acneiform nodules observed by the physician in a postadolescent patient who is not receiving corticosteroids
Positive pathergy test	Test interpreted as positive by the physician at 24–48 hours

The criteria were drawn up by the International Study Group for Behçet's disease.⁶⁶ For the diagnosis to be made, a patient must have recurrent oral ulceration plus at least two of the other findings in the absence of other clinical explanations.

subclinical until significant portions of the retina have been damaged. Skin lesions (Table 58.10) may include folliculitis and erythema nodosum, which (in contrast to the erythema nodosum of sarcoidosis and inflammatory bowel disease) has a tendency to ulcerate. In most cases, the “erythema nodosum” of Behçet’s disease is actually a medium-vessel vasculitis, rather than a septal panniculitis. Finally, the phenomenon of pathergy – the development of pustules at the sites of sterile needle pricks – occurs rarely except in Turks.⁶⁰

Manifestations of Behçet’s disease are not limited to those encompassed by the diagnostic criteria. For example, meningoencephalitis, which produces recurrent “sterile meningitis” with fever and encephalopathy, rivals uveitis as the most common cause of permanent disability. Strokes may also complicate Behçet’s disease. Additional features seen in some patients include peripheral arthritis (usually nondeforming, oligoarticular, involving large joints in an asymmetrical pattern), sacroiliitis, thrombophlebitis (often migratory), gastrointestinal disease (mimicking Crohn’s disease), epididymitis, coronary angiitis, and large-artery vasculitis.

Laboratory tests during active disease usually show mild leukocytosis, thrombocytosis, and an elevated ESR. The cerebrospinal fluid of patients with meningoencephalitis shows a lymphocytosis and elevated protein. Biopsies of the ulcers in the mouth, genital area, or colon show ulcerations and infiltration with mononuclear cells. Granulomas are not seen, a feature that helps to distinguish Behçet’s disease of the bowel from Crohn’s disease. Biopsies in other affected organs usually reveal vasculitis.

Treatment depends on the type and severity of the disease. Colchicine is sometimes effective for mild oral and genital ulcers. Severe disease in any organ system almost always requires high doses of prednisone (e.g., 1 mg/kg per day). Chlorambucil or cyclophosphamide is useful for the most severe forms of uveitis or meningoencephalitis. Azathioprine, Cyclosporine, methotrexate, IFN- α , and pentoxifylline have been reported to be effective in some patients. Of these latter agents, only azathioprine has been studied in large clinical trials. TNF inhibitors are reputed to be effective in at least some cases, but controlled trials of this approach are lacking. Because disease activity in Behçet’s disease tends to remit and relapse, drug therapy is slowly tapered once the patient improves.

■ BUERGER’S DISEASE ■

In 1908, Dr Leo Buerger reported pathological studies on the blood vessels obtained from 11 amputated lower extremities of patients with a disorder he termed ‘thrombo-angiitis obliterans.’⁶¹ Buerger wrote that the disorder usually occurred in young adults between the ages of 25 and 40, and was characterized by a thrombotic process in the arteries and veins, followed by organization and recanalization. Portions above and below the diseased segment appear normal.

Buerger proceeded to describe the typical presentation and evolution of this disorder, from the onset of ‘indefinite pains in the foot, in the calf of the leg, or in the toes, and particularly of a sense of numbness or coldness whenever the weather is unfavorable.’ The initially nonspecific symptoms of Buerger’s disease sometimes suggest a primary neuropathic process. Buerger observed that ‘Some of these cases give the typical symptoms of intermittent claudication.’ Upon the development of critical limb ischemia by the patient, Buerger described the development of a ‘blister, hemorrhagic bleb, or ulcer ... near the tip of one of the toes ... and when this condition ensues the local pain becomes intense.’ Finally, Buerger reported, the condition resulted in dry gangrene and often in amputation because of unbearable pain.

Except for the remarkably strong association of Buerger’s disease with the use of tobacco (see below), relatively little has been learned of this peculiar condition since the time of Buerger’s original description. The classic patient with Buerger’s disease is a young male who smokes cigarettes heavily. However, in populations where smoking is highly prevalent among females, Buerger’s disease may afflict women as well. Although Buerger’s disease has a predilection for the distal lower extremities, the distal upper extremities may also be severely involved.

Angiography of the extremities may suggest the diagnosis, but the findings are not pathognomonic (Fig. 58.14). The vessels most commonly involved are the digital arteries of the fingers and toes, as well as the palmar, plantar, tibial peroneal, radial, and ulnar arteries. Obliteration of these vessels leads to the development of collaterals that frequently have a ‘corkscrew’ appearance. Examination of the proximal vasculature by aortography is essential to exclude embolic sources and to demonstrate normality of the proximal vessels, which is characteristic of Buerger’s disease.

Buerger’s disease is unusual among the vasculitides in several respects: (1) the disease involves veins as well as arteries (even though the most striking symptoms are secondary to arterial involvement); (2) despite the intense involvement of medium-sized arteries, there is virtually no involvement of internal organs or any tissues besides the extremities; (3) although associated with the formation of a highly inflammatory thrombus, compared to other vasculitides there are fewer inflammatory changes within blood vessel walls, and fibrinoid necrosis is absent; and finally (4) Buerger’s disease is not responsive to immunosuppression.

Buerger’s disease does not occur in the absence of exposure to tobacco, usually large accounts of cigarette smoking. Once established, the disease may be maintained by even small exposures to tobacco (even smokeless tobacco or second-hand smoke), so cessation of smoking is essential in the treatment of this disease. Failure to stop smoking is associated with a dramatic increase in the risk of limb loss by amputation.⁶² Although smoking is necessary, it is clearly not sufficient on its own to cause Buerger’s disease. Other factors, including genetic factors and abnormalities of cellular and humoral immunity, are currently under investigation.

In addition to encouraging cessation of smoking in the strongest possible terms, the therapy of Buerger’s disease requires meticulous local wound care, avoidance of trauma to the involved areas, and ample use of narcotic analgesia. A variety of empiric therapies may be employed, including calcium channel blockers, pentoxifylline, iloprost, and sympathectomy, but there is currently little evidence to support their efficacy. The impact of anti-coagulation appears to be minimal. Thrombolytic therapies have not been studied in detail.

■ COGAN SYNDROME ■

In 1945, Cogan reported 4 young patients (aged 20–35) who presented with either nonsyphilitic interstitial keratitis (bilateral eye pain, erythema, and photophobia) or symptoms of severe inner-ear dysfunction (disabling vertigo, tinnitus, and progressive bilateral deafness). Regardless of which organ (eye or ear) became involved first, the onset of symptoms in one was followed within days to weeks by the development of symptoms in the other. Interstitial keratitis in the patients reported by Cogan waxed and waned, with only mild long-term ocular morbidity. In contrast, 3 of the 4 patients reported by Cogan suffered inexorable declines in auditory function, leading to deafness.

Fig. 58.14 Angiogram in Buerger's disease. Lower-extremity arteriogram in a 20-year-old woman with Buerger's disease. The anterior tibial artery attenuates in the mid-calf. The posterior tibial artery is occluded proximally, but is reconstituted above the ankle by collateral circulation from the peroneal artery. Distal to its reconstitution, the posterior tibial artery appears normal, consistent with the segmental nature of Buerger's disease.

Fig. 58.15 Interstitial keratitis in Cogan syndrome. Nonsyphilitic interstitial keratitis, demonstrated by slit-lamp examination in a patient with Cogan syndrome.

The combination of inflammatory eye disease and vestibulo/auditory dysfunction is the *sine qua non* of Cogan syndrome. The classic presentation is that of interstitial keratitis and sensorineural hearing loss. This disorder afflicts young adults, with no gender predominance. In approximately 10% of cases, eye and ear inflammation is associated with arthritis of medium- and large-sized vessels (including aortitis).^{63, 64} The ocular manifestations (and presumably the inner-ear disease) of Cogan syndrome are also vasculitic in nature.

Interstitial keratitis leads to the sensation of ocular irritation, excessive lacrimation, and photophobia, and is accompanied by moderate reductions (generally reversible) in visual acuity. The eye findings may be evanescent, and often require repeated examination for detection. Examination of the cornea by slit lamp (Fig. 58.15) reveals stromal clouding in the anterior and middle cornea. Pathologically, the cornea shows lymphocyte and plasma cell infiltration into the deep layers of the cornea, with varying degrees of neovascularization. Although nonsyphilitic interstitial keratitis is the ophthalmological hallmark of Cogan syndrome, virtually any type of inflammatory eye disease may occur in this disease, including conjunctivitis, uveitis, episcleritis, scleritis, exophthalmos, papilledema, retinal vasculitis, and inflammation of the optic papilla that suggests optic neuritis.

The greater cause of long-term morbidity in Cogan syndrome is the ear manifestations. Failure to recognize the nature of the problem promptly and institute appropriate therapy leads to more than half of the patients with Cogan syndrome suffering some degree of irreversible hearing loss. A substantial percentage become profoundly deaf in at least one, if not both, ears, and become candidates for cochlear implantation. Audiologic testing reveals sensorineural hearing loss. The vestibular manifestations may also be severe, and usually present with the abrupt onset of vertigo, ataxia, tinnitus, and nausea and vomiting. The severity of these symptoms is often sufficiently great to confine patients to bed. Vestibular dysfunction may lead to the disabling visual complaint of oscillopsia, in which patients perceive objects to jiggle back and forth.

Access to tissue at any stage of ear involvement in Cogan syndrome is rare. Consequently, knowledge of the pathology of this disorder stems mostly from temporal bone specimens from patients with long-standing, intensively treated disease. These findings include endolymphatic

hydrops, acute labyrinthitis resulting in atrophy of the hair cells and their supporting structures, focal or diffuse proliferation of fibrous tissue and bone (neo-osteogenesis), and neuronal degeneration. Once again, definitive evidence of vasculitis in these tissues is absent.

Medium- and large-vessel arteritis may lead to a host of complications in patients with Cogan syndrome, including aortitis, aortic regurgitation, coronary artery inflammation, mesenteric vasculitis, and limb claudication. The large-vessel disease of Cogan's syndrome must be distinguished from that of Takayasu's arteritis (Chapter 59).

Interstitial keratitis generally responds well to topical steroid therapy, which must often be administered chronically. In contrast, sensorineural hearing loss must be treated early and aggressively, with high doses of systemic glucocorticoids. Failure to institute such therapy within the first 2 weeks of symptoms frequently results in irreversible hearing loss. Most patients who will respond generally do so within 2 weeks. Cytotoxic agents such as cyclophosphamide may also be considered for either the eye or ear manifestations if sufficiently severe. Because of the recurrent nature of Cogan syndrome in many cases, the cumulative morbidity from treatment may be substantial. Once the disease is controlled, a moderate remission maintenance regimen should be considered, particularly in patients who have experienced disease flares before.

PRIMARY ANGIITIS OF THE CENTRAL NERVOUS SYSTEM

Primary angiitis of the central nervous system (PACNS), a rare disease of unknown etiology, is characterized by small- and medium-sized vessel vasculitis limited to the brain or spinal cord.⁶⁵ Some authors prefer the term 'isolated angiitis of the central nervous system.'⁶⁶ The once commonly used label 'granulomatous angiitis' has dropped out of favor because not all patients with vasculitis limited to the central nervous system demonstrate granulomatous inflammation, and other forms of vasculitis, including systemic diseases such as sarcoidosis and WG, can cause granulomatous vasculitis in the brain. Vasculitis limited to the central nervous system is the most difficult form of vasculitis to diagnose accurately. The protean manifestations of the disease, the unreliability of noninvasive diagnostic tests, and the difficulty of obtaining adequate brain biopsies all contribute to the diagnostic conundrum of PACNS.

Classically, patients with PACNS manifest the triad of headache, encephalopathy, and multifocal strokes. However, only a minority of patients present with all three features, and many develop a wide range of other neurological manifestations. Most patients present in the fourth or fifth decade of life, but may range in age from 3 to 74. The disease affects women and men equally often. The disease can begin suddenly or develop slowly. The first symptom is usually headache, often severe and sometimes associated with nausea and vomiting. Almost all patients eventually develop encephalopathy with lethargy, confusion, and memory loss. Some develop multifocal strokes, seizures, evidence of increased intracranial pressure, or myelopathy. Constitutional symptoms, a hallmark of most forms of vasculitis, are notably absent in patients with PACNS.

In keeping with the isolated nature of the inflammation of PACNS, routine laboratory tests are usually normal. The majority of patients do not have anemia or an elevated ESR. The lumbar puncture yields abnormal cerebrospinal fluid in approximately 80% of cases: the most common abnormalities are a modest cerebrospinal fluid monocytoysis and an increased cerebrospinal fluid protein. Oligoclonal bands and elevated

Fig. 58.16 Cerebral angiogram in primary angiitis of the central nervous system. The angiogram illustrates the typical dilations and narrowing of arteries.

IgG indices in the cerebrospinal fluid do not appear to be either sensitive or specific for PACNS.

The clinical and laboratory features described above apply to patients who are diagnosed by brain biopsy. Over the last 30 years, an increasing number of cases have been reported in which the diagnosis is based on central nervous system angiography alone, without the performance of a brain biopsy.⁶⁷ These patients differ from those with biopsy-confirmed cases in that the majority are women, the onset tends to be more abrupt, the neurological signs less severe, and the lumbar puncture normal.

Of the noninvasive imaging tests, magnetic resonance imaging (MRI) is more sensitive than computed tomography (CT).^{68, 69} The false-negative rate of MRI appears to be less than 10% in most series. Most commonly the MRI shows multiple, bilateral, bland infarctions, distributed in the subcortical white matter, cortical gray matter, deep gray matter, deep white matter, or cerebellum. Hemorrhagic lesions and mass lesions also occur. No MRI pattern is specific for PACNS. The classic abnormality on angiography is the "string of beads" pattern produced by segmented arterial narrowing alternating with dilatations (Fig. 58.16). Vascular occlusions, collateral formation, and prolonged circulation time may also be seen. Microaneurysms, so frequently seen on visceral angiograms in patients with PAN, rarely occur in PACNS. Unfortunately, no angiographic pattern is pathognomonic, and other disorders, including intravascular lymphoma, systemic infections, and vasospasm can produce similar angiographic abnormalities (see below). Indeed, in one study of 35 patients who had undergone angiography and brain biopsy because of suspected PACNS, no patient with a "classic" angiogram had a positive biopsy. Conversely, none who had a positive brain biopsy for vasculitis had a classic angiogram.⁷⁰ Angiograms are falsely negative in about 35% of patients with PACNS.⁶⁵

The diagnosis of PACNS is definite if the patient: (1) presents with multifocal strokes or encephalopathy accompanied by headache; (2) has a cerebral angiogram showing changes consistent with vasculitis; (3) has no evidence of systemic infection, neoplasm, or toxic exposure; and (4) has a biopsy of the leptomeninges or brain cortex demonstrating vasculitis in the absence of other causes. The diagnosis of PACNS should be considered possible when the patient meets all criteria except that of a positive brain biopsy. In patients not having a positive biopsy, systemic vasculitides and other diseases that can mimic vasculitis must be excluded.

Histological specimens in PACNS show vasculitis of small and medium-sized leptomeningeal and cortical arteries. Veins and venules are involved less often. The inflammatory infiltrate varies, but consists predominantly of lymphocytes admixed with histiocytes. Langerhans and foreign-body giant cells occur in about half of the cases. The inflammation usually targets the intima and media and produces variable degrees of necrosis.

The rarity of PACNS has prevented prospective treatment trials. Prednisone and cyclophosphamide are recommended for patients who have severe neurological deficits and a positive brain biopsy. Prednisone alone (beginning at 1 mg/kg per day) appears to be adequate therapy for some patients, especially those who experience a sudden onset of mild to moderate abnormalities that are not progressive, have a normal cerebrospinal fluid, and whose diagnosis is supported by an angiogram in the absence of a brain biopsy. Mortality rates, once as high as 95% in untreated patients, have plummeted to less than 10% for treated patients. Most patients improve with treatment; the degree of recovery correlates inversely with the severity of deficits at diagnosis and the age of the patient.

URTICARIAL VASCULITIS

In 1973, Mayo Clinic investigators described 4 patients with recurrent attacks of urticarial lesions and combinations of synovitis, abdominal symptoms, and glomerulonephritis.⁷¹ Although transient, urticaria in these patients generally persisted for at least 24 hours (longer than the 6–8 hours typically associated with chronic idiopathic urticaria) and sometimes left traces of hyperpigmentation, indicative of red blood cell extravasation through damaged capillaries. Low complement levels were present in all of the patients during periods of active disease, and skin biopsies demonstrated evidence of an IC-mediated disease process. Investigations excluded SLE and mixed cryoglobulinemia, leading to the report of a previously undescribed disorder now known as the hypocomplementemic urticarial vasculitis syndrome (HUVS).

HUVS is now recognized as one of a group of disorders known as urticarial vasculitis. At least three subtypes of urticarial vasculitis are known⁷²: (1) a normocomplementemic form, which is generally idiopathic and benign; (2) a hypocomplementemic form, which is often associated with a systemic inflammatory disease; and (3) HUVS, a potentially severe condition usually associated with autoantibodies to the collagen-like region of C1q. Most patients with urticarial vasculitis have the hypocomplementemic subtype and demonstrate low C3, C4, and CH50. Patients with urticarial vasculitis who show evidence of complement activation are much more likely to manifest signs of a systemic disorder than those with normal complement levels. The majority of urticarial vasculitis patients (80–90%) have an underlying systemic disorder, usually SLE, Sjögren's syndrome, or cryoglobulinemia.

Fig. 58.17 Immunofluorescence study of a skin biopsy from a patient with hypocomplementemic urticarial vasculitis syndrome (HUVS). There is positive staining for immunoglobulin G along the basement membrane and around small arteries in the dermal papillae.

The lesions of urticarial vasculitis must be distinguished from chronic idiopathic urticaria, which is encountered far more commonly in clinical practice. Only about 10% of patients with chronic urticaria have urticarial vasculitis. In contrast to chronic idiopathic urticaria (the principal symptom of which is pruritus), urticarial lesions associated with vasculitis are often accompanied by stinging or burning. Urticarial vasculitis affects the capillaries and postcapillary venules, and the classic features of leukocytoclastic vasculitis may be evident on light microscopy. IF reveals both immunoglobulin and complement deposition in or around blood vessels of the upper dermis and/or the dermal–epidermal junction (Fig. 58.17).

HUVS frequently mimics SLE. As with SLE, HUVS has a striking female predominance, with a female-to-male ratio of 8:1. However, SLE-specific antibodies (e.g., those to dsDNA and the Sm antigen) do not occur in HUVS, and there are several distinguishing clinical features. For example, HUVS may be associated with angioedema, ocular inflammation, and chronic obstructive pulmonary disease (COPD), all of which are highly atypical of SLE. Although exacerbated by tobacco use, COPD may occur in the absence of any history of cigarette smoking, and may be severe. The few cases of lung biopsies in patients with this complication have not demonstrated vasculitis, but rather have shown panacinar emphysema. As in SLE, kidney biopsies in HUVS patients may reveal mesangial inflammation or membranoproliferative glomerulonephritis, but progression to end-stage renal disease in HUVS is unusual. Severe cardiac valve disease and Jaccoud's arthropathy have also been reported in HUVS.

Most patients with HUVS make C1q precipitins, i.e., IgG autoantibodies to the collagen-like region of C1q.⁷² Whether or not anti-C1q antibodies contribute to the pathogenesis of HUVS remains unclear. Anti-C1q antibodies are also detected in up to one-third of patients with SLE, and in more than 80% of SLE patients with glomerulonephritis. Despite the prevalence of these antibodies in SLE, few patients who are seropositive for anti-C1q antibodies develop urticarial lesions. Glomeruli from patients with lupus nephritis may contain large quantities of anti-C1q antibodies.

Fig. 58.18 Coronary angiogram in a 38-year-old patient with history of Kawasaki's disease as a child. Febrile illness at the age of 4 led to coronary artery aneurysms, one of which thrombosed at the age of 38, leading to a myocardial infarction.

The natural history of urticarial vasculitis is difficult to predict. Some cases, particularly those with normal complement levels during attacks, are self-limited and require little therapy. Other cases, especially HUVS, may cause life-threatening involvement of the lungs or other organs, and require periods of intensive immunosuppression. The rarity of HUVS means that there exists little consensus regarding the optimal therapeutic strategy, and treatment decisions must be individualized according to each patient's clinical status. For hypocomplementemic urticarial vasculitis limited to the skin, antimalarial agents, dapsone, and low doses of glucocorticoids may be useful.

KAWASAKI'S DISEASE

The first case of the disease now known as Kawasaki's disease was described in 1939^{73,74} and involved a 5-year-old girl who presented with high fever, sore throat, and rash and subsequently died from rupture of a coronary artery aneurysm. In 1961, Tomisaku Kawasaki evaluated a Japanese child with similar disease features, and also noted prominent cervical adenopathy. Over the next 6 years he performed a careful clinical and epidemiological study of the new disorder, and eventually reported the disease in the Japanese literature as 'mucocutaneous lymph node syndrome' in 50 patients.^{74,75} Formal diagnostic criteria for Kawasaki's disease have been developed.⁷⁶ The disease has a predilection for Asian children, but occurs in all races. Eighty percent of all cases occur in children younger than 5 years of age. The annual attack rate in Japan is approximately 80–90 cases per 100 000 children under the age of 5, compared to roughly 10 per 100 000 among Caucasian children in the USA.⁷⁷

In all of the patients described initially by Kawasaki, the symptoms resolved without sequelae within 1 month. In subsequent years, however, mortality from cardiac complications (usually coronary artery thrombosis) was reported. Cardiac complications of Kawasaki's disease result from a severe panvasculitis, leading to narrowing of the coronary lumina by the migration of myointimal cells from the media through the fragmented internal elastic lamina. Although catastrophic heart complications occur in only a small minority of patients, evidence suggests that the preponderance of patients with Kawasaki's disease have at least some cardiac involvement. Heart lesions may include myocarditis, pericarditis, aneurysmal dilatation and thrombosis of the coronary arteries, and myocardial infarction (Fig. 58.18). The tropism of the vascular inflammation for coronary arteries and its unusual propensity to cause aneurysm formation remain unexplained. The prompt institution of high-dose intravenous immunoglobulin (IVIG) may prevent this complication (see treatment, below).

Certain clinical features of Kawasaki's disease (fever, conjunctivitis, stomatitis, erythema multiforme-like rash, and the overwhelming predominance of the disease in young children) bear strong resemblance to a number of childhood exanthems. Moreover, the disease epidemiology of Japanese outbreaks is reminiscent of the classic spread of infectious agents. However, the profound disturbances of immunoregulation in Kawasaki's disease, e.g., the unusual degree of T-cell and monocyte activation, far exceed the abnormalities accompanying most other febrile childhood illnesses. Skewing of the T-cell receptor V β distribution has been reported by some investigators, but not confirmed by others. The degree of immune activation in Kawasaki's disease and the acute but generally self-limited nature of the illness have implicated superantigens in the disease pathogenesis (Chapter 6). Substantial attention has focused on toxic shock syndrome toxin-1 (TSST-1), an exotoxin produced by *Staphylococcus aureus*, but the true relationship of this and other potential superantigens to the etiology of Kawasaki's disease remains unclear.

Before the availability of effective therapy, at least 20% of patients with Kawasaki's disease developed coronary aneurysms and 2% succumbed to the disease. To confirm earlier reports of efficacy of IVIG in Kawasaki's disease, seven pediatric centers in the USA enrolled 168 children with acute disease into a randomized trial. Half of the patients received IVIG 400 mg/kg per day on four consecutive days plus high-dose aspirin (100 mg/kg per day), and the other half received aspirin alone.⁷⁸ IVIG reduced the incidence of coronary aneurysms by 78% and relieved the symptoms of Kawasaki's disease with dramatic swiftness, establishing the combination of IVIG and aspirin as the standard for therapy of Kawasaki's disease. The mechanism of action of IVIG in this disorder remains unknown, but the rapidity of its benefit has implicated an anti-cytokine effect. The optimal dose of IVIG in Kawasaki's disease has not been defined: meta-analyses suggest a lower rate of coronary aneurysms in patients who receive higher IVIG doses.

Large-vessel vasculitides

Cornelia M. Weyand, Jörg J. Goronzy

59

Whereas most tissues have compensatory mechanisms that allow them to sustain the damaging effects of acute and chronic inflammation, this is not the case for the body's main blood vessels. Medium and large arteries are organs without redundancy and regenerative capacity; their uncompromised function is required to sustain life. Accordingly, inflammatory damage to such arterial vessels leads to severe clinical consequences, immediately posing a threat for the loss of vital functions. When affected by inflammation, the aorta and its branches have two possible response patterns: inflammatory destruction of the vessel wall leads to dilatation, aneurysm formation, and, infrequently, dissection and hemorrhage; or the inflammation initiates an injury response that results in luminal occlusion, disruption of blood supply, and ischemic damage of dependent organ structures.

In contrast to other vasculopathies, especially those related to atherosclerosis, vasculitides of the larger blood vessels are almost always associated with a syndrome of intense systemic inflammation.¹ Recent evidence has challenged the traditional view that systemic inflammation represents a spill-over of inflammatory mediators from the vasculitic lesions. Instead, systemic activation of the innate immune system may be an early event and initiate the processes leading to vessel wall inflammation. The coincidence of malaise, fever, wasting, and myalgias with signs of ischemia due to vascular failure remains a critical clue for the physician when diagnosing and treating large-vessel vasculitis.

The two major forms of large-vessel vasculitis are giant-cell arteritis (GCA) and Takayasu arteritis (TA). In addition, aortitis can infrequently be seen in other diseases, such as infections, connective tissue diseases, sarcoidosis, and inflammatory bowel disease; and, occasionally, also as an idiopathic syndrome. Polymyalgia rheumatica (PMR) is a condition closely related to GCA, occurs in the same patient population, and often precedes or follows the clinical diagnosis of GCA.² Patients with PMR do not have typical vascular lesions, but have a systemic inflammatory syndrome indistinguishable from GCA. About 10% of PMR patients will eventually progress to full-blown vasculitis. Similarities in the vascular lesions of GCA and TA have supported the concept that the immunopathogenesis of these vasculitides is analogous. Whether the systemic inflammatory reactions accompanying GCA, TA, and PMR have disease-specific elements remains unknown. Excellent progress has been

made in unraveling the pathogenesis of GCA over the last decade, and this will inevitably lead to improvements in diagnosis, long-term management, and broadening of the therapeutic armamentarium.

■ EPIDEMIOLOGY ■

GCA may be a very old disease, as suggested by historic evidence that more than 1000 years ago removal of the temporal artery was recommended by a physician in Baghdad. In 1932, Horton and colleagues at the Mayo Clinic in Minnesota recognized that GCA was an inflammatory vasculopathy when they found dense inflammation in the temporal arteries of two systemically ill patients with severe headaches. The first reports of TA, or 'pulseless disease,' in young women surfaced in Japan in the 19th century. The syndrome was named after Dr. Takayasu, an ophthalmologist who in 1905 described peculiar optic fundus abnormalities.

The strongest risk factor for GCA, TA, and PMR is age.^{3,4} GCA and PMR are essentially absent in individuals younger than 50 years of age, and their incidence climbs continuously during the 7th and 8th decades of life. TA is exclusively diagnosed in individuals younger than 40 years of age, with peak incidence during the 2nd and 3rd decades of life. All three syndromes affect women much more often than men, with a 2:1 ratio in PMR and GCA and a 9:1 ratio in TA.^{3,4}

Marked geographic variations in the incidence and prevalence of GCA, TA, and PMR have given rise to speculations about environmental exposures as key factors in disease pathogenesis. GCA is the most frequent vasculitis in the western world, with yearly incidence rates reaching 10–20 cases per 100 000 persons over 50 years of age.³ In general, PMR is diagnosed three- to fourfold more frequently, with a prevalence of up to 1 case per 133 individuals older than 50.² Iceland, Norway, Sweden, and Denmark are high-risk areas; also, higher incidence rates are maintained in Scandinavian immigrant populations in the USA. The risk is significantly lower in Hispanics and African-Americans. Although TA can afflict all races, a predilection exists for individuals of Asian, and Central and South American origins. Japan, Thailand, India, Turkey, and nations in Central and South America are considered high-incidence

CLINICAL PEARLS

CLINICAL AND EPIDEMIOLOGIC CLUES
IN GIANT-CELL ARTERITIS

- >> Patient older than 50 years of age
- >> Female
- >> Northern European heritage
- >> Laboratory findings of a highly activated acute-phase response
- >> Insidious onset of nonspecific symptoms (weight loss, night sweats, malaise, fever)
- >> Ischemia of ocular structures, cranial muscles, scalp, or upper extremities

regions. TA is a rare disease with an annual incidence of 1–2 cases/million. The typical patient is a female in her 20s to 30s. In middle-aged men and women, it can be challenging to differentiate TA from rapidly progressing atherosclerotic disease, especially as both disease processes may coexist.⁵

ETIOLOGY AND PATHOGENESIS

Vasculitides affecting medium and large human arteries are caused by dysregulated immune responses.^{1,6,7} Studies from the last decade have revealed that vasculitis involves a combination of multiple effector mechanisms used by the innate and adaptive immune systems. Inflammation is a critical host defense response protecting against infection and tissue injury, but it invariably contributes collateral damage to the very tissue site in which it intends to destroy microbes and remove the injured self. If initiated in the absence of an instigator or persistent stimulus, despite the successful removal of the inciting infection or injury, inflammation will eventually become the cause of disease as tissue damage accumulates and, in the case of vasculitis, will leave the host with malfunctioning arteries.

The similarities in the tissue tropisms and the histologic lesions of GCA and TA suggest overlapping disease pathways, justifying their discussion in the context of either disease. Marked progress has been made in understanding early and late events in GCA from studies focusing on a human artery-severe combined immunodeficiency (SCID) mouse model. The etiopathogenesis of PMR is less well understood, but experimental evidence suggests that it represents a *forme fruste* of GCA in which inflammatory attack to the vessel wall remains below a threshold, and standard histology describes noninflamed arteries.

THE HUMAN ARTERY-SCID MODEL
OF VASCULITIS

The unique components of GCA/TA pathogenesis are chronically persistent inflammatory infiltrates settled within the wall of arteries with three distinct layers and well-developed elastic membranes. To overcome limitations encountered in animal models of vasculitis, which cannot mimic the vessel size, vessel wall structure, or aging

component of the host, a novel experimental model for GCA was established by implanting GCA-affected or normal human arteries into immunodeficient mice. Within 1 week, the human arteries are engrafted and supplied with blood through their vasa vasorum trees.⁸ Chimeras can then be treated with cell-depleting antibodies, anti-cytokine reagents, or with adoptive transfer of immuno-inflammatory cells. This model has been extremely helpful in deciphering which cells and mediators sustain vasculitis. Equally importantly, the model has allowed for vasculitis induction in normal arteries, thereby illustrating the early pathogenic steps that precede establishment of granulomatous mural lesions.⁹

EARLY STEPS IN VASCULITIS

Normal human arteries of the medium and large categories are not immunologically inert. To the contrary, they possess populations of dendritic cells (DC) distributed amongst wall-residing cells.¹⁰ Among these vascular DCs, a population strategically positioned at the media-adventitia border has been implicated in initiating wall inflammation.¹¹ In contrast to other DC-containing tissues, normal human arteries do not elicit T-cell stimulation when implanted into SCID mice. This immunologic quiescence, despite being equipped with DC networks, has given rise to the hypothesis that the primary function of vascular DCs lies in maintaining a very high threshold for the induction and persistence of adaptive immune responses. A principal role for vascular DCs in functioning as tolerance inducers would fit well with the host's need to avoid inflammatory damage in such critical and nonregenerative organs as arteries.

The tolerant state of vascular DCs can, however, be broken if the artery is exposed to a microbial environment (Fig. 59.1). Human arteries detect infections through Toll-like receptors (TLR) expressed on vascular DCs.¹² TLRs are a family of pattern recognition receptors employed by nature to detect motifs shared by groups of bacterial and viral microorganisms. By sensing common microbial structures through their TLRs, DCs initiate the first line of defense against infections. Injection of lipopolysaccharide, a moiety conserved across Gram-negative bacteria, into human artery-SCID chimeras, leads to robust activation of wall-residing DCs and is sufficient to initiate adaptive immune responses (Fig. 59.2).¹³ Specifically, CD4 T cells are recruited to the vessel, migrate toward the adventitia-media junction, receive activating signals, and undergo *in situ* activation. Arteries harvested from patients with PMR, despite having no sign of inflammation, have mature DCs and do not require exposure to lipopolysaccharide. Spontaneously, they recruit and activate T cells from co-implanted and human leukocyte antigen (HLA)-matched GCA arteries.⁹ Thus, DC maturation is a very early step in the initiation of vasculitis, occurring long before the chronic phase of wall inflammation.

The potential of pathogen-derived molecules to start inflammatory responses in arterial tissues has rekindled old discussions on whether vasculitis is elicited by infection. In this context it is important to mention that recurring reports of finding infectious organisms in inflamed temporal arteries from GCA patients have failed to find confirmation in more comprehensive studies.⁹ If the role of microbial agents is to stimulate adventitial DCs, the presence of the organism in the affected artery is obviously not necessary, but infections located elsewhere in the patient may still have a facilitating role in disease initiation.

Fig. 59.1 Pathogenic pathways in giant-cell arteritis (GCA). Under physiologic conditions, dendritic cells (DCs) in the adventitia are immature and resting. In polymyalgia rheumatica and GCA, adventitial DCs undergo activation with the induction of co-stimulatory ligands and chemokines. Under experimental conditions, adventitial DCs can be triggered with Toll-like receptor ligands, e.g., pathogen-derived molecules.

Fig. 59.2 Pathogenic pathways in giant-cell arteritis (GCA). CD4 T cells are recruited to the adventitia of blood vessels by activated dendritic cells and undergo *in situ* stimulation. Interferon- γ is a key cytokine in GCA and regulates activation of macrophages and other proinflammatory pathways.

KEY CONCEPTS

- >> Medium and large human arteries have multiple wall layers and a wall structure substantial enough to be the target of transmural inflammation
- >> Vasculitis causes the rapid and concentric growth of hyperplastic intima, leading to luminal occlusion and ischemia of dependent tissues. Intramural inflammation of the aorta may occasionally result in wall damage followed by aneurysm formation and rupture
- >> Due to the vital function and nonregenerative nature of large human arteries, the threshold for the induction and persistence of innate and adaptive immune responses in the wall structures of such arteries must be explicitly high
- >> Inflammatory infiltrates typical for granulomatous vasculitis enter the vessel from the 'back door,' the adventitia, and not from the lumen
- >> Besides their critical role in securing blood flow, medium and large blood vessels also possess immunoregulatory functions mediated by dendritic cells indigenous to the vascular wall

ADAPTIVE IMMUNE RESPONSES IN GIANT-CELL ARTERITIS

Chronic inflammatory infiltrates occupying all layers of the affected artery are comprised of CD4 T cells, a few CD8 T cells, and macrophages. Typically, these cells form granulomas. Multinucleated giant cells

are found in about 50% of patients and are often localized close to the intima-media border adjacent to the lamina elastica interna. Fragmentation of that elastic membrane is a hallmark of GCA. Functionally important products of CD4 T cells include interferon- γ (Fig. 59.2), the tissue level of which correlates closely with patterns of clinical manifestations.¹⁴ Maintenance of the complex granulomatous arrangements also requires T cells. Even the process of neoangiogenesis, which is necessary to promote the growth of the lumen occlusive neointima, is closely correlated with interferon- γ levels, thus assigning a key position to this T-cell product in multiple interrelated disease processes.¹⁵ In TA, direct cytotoxic function of CD8 T cells, natural killer cells, and $\gamma\delta$ T cells has been implicated in local tissue injury.¹⁶

CD4 T cells continue to receive instructive signals from DCs even in chronically established disease since DC depletion effectively disrupts granulomatous inflammation.⁹ In mature vasculitic lesions, DCs are the sole producers of CCL19 and CCL21, chemokines implicated in T-cell recruitment. Also, they express CD86 and thus provide necessary co-stimulatory signals to maintain T-cell responses.¹¹ Naturally, the question of whether a unique antigen exists that drives adaptive immune responses in GCA has been raised. Studies with T-cell lines established from inflamed temporal arteries have suggested that the T-cell populations are nonrandom and clonally selected. Identical CD4 T cells dominating the inflammatory infiltrate in the right and left temporal arteries of patients with bilateral biopsies have added weight to these findings.¹⁷ The spectrum of possible antigens includes microbes, products of injured or stressed cells, and altered self. An alternative hypothesis puts emphasis on the uniqueness of the tissue compartment and the dysfunction of T-cell homeostasis and T-cell regulation in the aged host, and considers ordinary self antigens as sufficient to drive these misplaced immune responses.^{1,12}

Fig. 59.3 Pathogenic pathways in giant-cell arteritis (GCA). Fully developed GCA is a panarteritis with transmural T-cell and macrophage infiltrates. Macrophages in different wall layers commit to distinct damage pathways involving production of proinflammatory cytokines, reactive oxygen intermediates (ROI), metalloproteinases, or growth factors. Multinucleated giant cells also provide growth and angiogenic factors that promote intimal hyperplasia and luminal occlusion.

IMMUNE-MEDIATED TISSUE INJURY AND THE ARTERY'S CONTRIBUTION TO VASCULAR FAILURE

Accumulated data support the premise that a major part of the tissue injury in the arterial wall is actually mediated by macrophages (Fig. 59.3).¹ Remarkably, wall-invading macrophages commit to selected pathways of maturation according to their placement in the wall structure.¹⁸ Macrophages positioned in the adventitia mainly produce proinflammatory monokines, such as interleukin-6 (IL-6) and IL-1 (Fig. 59.2). Their major function may lie in supporting ongoing T-cell responses. Intimal macrophages have been described to express nitric oxide synthase, and peroxynitrite generation has been associated with endothelial dysfunction.¹⁹ Macrophages captured in the medial smooth-muscle cell layer have a portfolio of tissue-damaging functions (Fig. 59.3).^{20,21} They release metalloproteinases, likely contributing to digestion of the elastic structures. They are potent in secreting reactive oxygen species, facilitating oxidative damage to smooth-muscle cells and endothelial cells. Most importantly, they are the source for platelet-derived growth factor and vascular endothelial growth factor.^{15,22} Through providing these growth and angiogenesis factors, macrophages support wall-resident cells in their injury response pattern. Myofibroblasts migrate towards the intima, proliferate, and produce matrix. The unfortunate consequence is

intimal hyperplasia, the essential mechanism underlying luminal stenosis and vascular failure. Notably, in both GCA and TA, destruction of the arterial wall with subsequent rupture and hemorrhage is the exception. Instead, a fast, concentric, and almost complete intimal hyperproliferation leads to obstruction of the lumen and ischemic damage of dependent organs. Not all GCA patients develop vascular stenosis. In these patients mural inflammation does not lead to intimal hyperplasia and the lumen is maintained. Patients with nonobstructive vasculitis have a distinct clinical presentation; vascular malfunction is not noticeable but they have an intense systemic inflammatory syndrome.

Failure of the inflamed arteries, presenting as lumen obstruction, would not be possible without the active contribution of the arterial wall residents. Proliferating myofibroblasts, rather than immune cells, build the scaffold of the lumen-obstructive neotissue.²² Also, neoangiogenesis effectively supports the artery's response-to-injury reaction, supplying oxygen and nutrients to the thickening wall.¹⁵ In essence, the immune system emerges as an instructor to a maladaptive response of the vessel itself. The critical participation of vascular components may provide an explanation for the stringent tissue tropism of large-vessel vasculitides, which selectively target certain vascular territories.

CLINICAL FEATURES IN GIANT-CELL ARTERITIS

Clinical manifestations of GCA reflect the combination of a systemic inflammatory syndrome with vascular insufficiency (Table 59.1).^{2, 23} Depending on the preferred target of vascular inflammation, patients fall into the category of either cranial GCA or large-vessel GCA. In addition, there exists another subpopulation of patients in whom the clinical consequences of arterial inflammation are minimal, and they come to clinical attention with a wasting syndrome.

In cranial GCA, symptoms result from vascular stenosis of the neck and head arteries, most prominently in the branches of the external carotid artery. Arteritis of the scalp arteries leads to the typical presentations of headaches and scalp tenderness. Patients report difficulties with wearing glasses or combing their hair. The headaches are often intense and unresponsive to standard analgesics. Headaches are a nonspecific clinical symptom, yet in a patient of the appropriate age with other findings indicating an inflammatory syndrome, physicians need to complete a workup for GCA. Insufficient blood flow to the masseter muscles and the tongue causes jaw claudication, elicited by prolonged chewing and talking. Although this type of claudication is present in less than 30% of patients, it is clinically helpful as it rarely occurs outside GCA. Similarly, painful dysphagia can be a useful clinical clue.

The orbita and the optic nerve are strictly dependent on blood supply from the external carotid system, particularly the ophthalmic artery. GCA in branches of the ophthalmic artery, specifically the posterior ciliary arteries, leads to anterior ischemic optic neuropathy, presenting as sudden and painless vision loss. Typically patients lose vision in the early-morning hours or wake up blind. Involvement of one eye may be followed by visual loss in the partner eye if the disease is not diagnosed and treated promptly. Besides anterior optic neuropathy, GCA can cause a number of ischemic complications in the orbita and along the visual axis, which may present as diplopia or partial vision loss. If recognized and treated immediately, vasculitis-associated sight loss is preventable, thus making GCA an ophthalmologic emergency.

Table 59.1 Clinical features of giant-cell arteritis (GCA), polymyalgia rheumatica (PMR), and Takayasu arteritis (TA)

Organ system	Clinical features	Frequencies		
		GCA	PMR	TA
Vascular	Headaches	***		*
	Limb claudication	*		***
	Scalp tenderness	**		
	Jaw claudication	**		
	Absent or asymmetric pulses	*		***
	Asymmetric blood pressure readings	*		***

	Normochromic or hypochromic anemia	**	*	**

Key: *** = high frequency (>70%); ** = moderate frequency (20–70%); * = low frequency (<20%).

Chronic nonproductive cough has been suspected to be related to arteritis in branches of the pulmonary arteries. If the vertebral and basilar arteries develop vasculitic stenosis, ischemia of the central nervous system manifests with transient ischemic attacks or frank stroke.

In patients with large-vessel GCA, cranial symptoms may be minimal, and temporal artery biopsy is often negative.²⁴ Instead, vascular insufficiency is focused on the upper-extremity vessels and the aorta. In rare cases, lower extremities are affected. Typically, patients have asymmetric blood pressure readings or totally lose upper-extremity blood pressures and pulses. The underlying lesions are occlusions in

the distal subclavian arteries, often extending into the axillary sections (Fig. 59.4). Patients with subclavian GCA are on average about 10 years younger at disease onset than are those with dominant cranial manifestations. Diagnosis of large-vessel GCA can be delayed as symptoms are nonspecific, and the systemic inflammatory component is less pronounced. Ischemic pain in the hands when using the arms is often combined with coolness and bluish discoloration. Gangrene of the fingertips is rare. Disability can be significant, as patients have difficulties with activities of daily living. With stenotic lesions of the subclavian arteries, blood pressure readings can be unreliable or totally

Fig. 59.4 Involvement of the subclavian axillary artery in giant-cell arteritis. Angiography of aortic arch and primary branches shows luminal irregularities in both distal subclavian arteries (**A**). The digital subtraction angiogram focuses on the left subclavian axillary junction and demonstrates a high-degree, long-segment stenosis that is smooth-walled and tapered (**B**). Newly formed collateral vessels branching off the distal subclavian supply blood to the arm.

absent, requiring alternative strategies for blood pressure monitoring. Although carotid involvement is considered infrequent, it can be challenging to distinguish atherosclerotic and vasculitic disease clearly. Patients with carotid GCA are at high risk for cerebral ischemic events. Aortic involvement preferentially targets the thoracic aorta and infrequently the abdominal aorta (Fig. 59.5). Dilation of the aortic root

Fig. 59.5 Aortic aneurysm in giant-cell arteritis. A three-dimensional reconstruction of a magnetic resonance angiography demonstrating wall irregularities and ectasia throughout the thoracic aorta of a 63-year-old female with biopsy-proven giant-cell arteritis is shown. The ascending aorta appears most affected. The origins of the subclavian and innominate arteries are dilated, indicating inflammatory damage of the wall. Mild irregularities of the subclavian apex are seen, without evidence for stenosis.

may lead to aortic insufficiency. Aortic aneurysms are often clinically silent. The diagnosis may first be made from tissue obtained surgically during aortic aneurysm repair. In extreme cases, the aortic wall ruptures.

The response pattern of arteries to wall inflammation may not include intimal hyperplasia, thus sparing luminal compromise and vascular failure. In such patients, the systemic inflammatory component dominates the clinical presentation. Fever, fatigue, malaise, weight loss, and depression are intense enough to prompt a workup for a malignancy. GCA needs to be on the list of differential diagnosis in all cases of fever of unknown origin, particularly in elderly individuals. Whereas patients with cranial GCA have abnormally thick and tender temporal arteries exhibiting nodularity and loss of pulses, clinical findings in non-stenosing GCA can be bland and unremarkable. Temporal artery biopsy should be pursued even if clinical examination does not suggest the diagnosis.

CLINICAL FEATURES IN POLYMYALGIA RHEUMATICA

PMR is diagnosed in patients presenting with pronounced stiffness and pain in the shoulder and pelvic girdle muscles (Table 59.1).² Laboratory testing shows a systemic inflammatory syndrome; arterial biopsy is

Table 59.2 Takayasu arteritis: relationship between clinical symptoms and affected vascular territories

Vascular bed involvement	Approximate frequency (%)	Predominant clinical symptoms
Subclavian	90	Arm claudication, pulselessness
Common carotid	60	Visual defects, strokes, transient ischemic attack, syncope
Abdominal aorta	45	Claudication, hypertension, abdominal angina
Renal	35	Hypertension
Aortic arch/root	35	Aortic insufficiency, congestive heart failure
Vertebral	35	Dizziness, visual impairment
Celiac axis	20	Abdominal angina
Superior mesenteric	20	Abdominal angina
Iliac	20	Claudication
Pulmonary	10	Dyspnea, chest pain
Coronary	10	Myocardial infarction, angina

negative for arteritis. It is estimated that about 10% of PMR patients who have no signs of vascular inflammation will eventually develop full-blown vasculitis. Notably, PMR often occurs in patients with GCA and is present in about 40% of GCA patients at disease onset. Tapering of immunosuppressive therapy in GCA is frequently associated with new or remittent PMR symptoms.²⁴ Complaints are focused on muscle pain and stiffness, classically affecting the neck, the shoulder girdle, and the pelvic girdle. Muscles of the torso may be involved. Peripheral arms and legs are spared. Muscle pain is most intense in the early morning and improves during the day. Inability to get out of bed, stand up from a chair, or get off the toilet seat should alert the physician to consider PMR. Some patients with PMR have synovitis or bursitis in their shoulder and hip joints,^{2,25} making them difficult to distinguish from those with seronegative rheumatoid arthritis. No diagnostic procedure is available that allows for the diagnosis of PMR; the syndrome remains an exclusion diagnosis in cases of myalgia combined with laboratory signs of systemic inflammation. On clinical examination, passive motion of shoulder and hip joints is maintained, but active motion is restricted due to pain. Muscle strength is normal. Careful evaluation of the temporal arteries is warranted to avoid missing fully developed GCA.

CLINICAL FEATURES IN TAKAYASU ARTERITIS

The clinical manifestations of TA are diverse and depend on the vascular territory preferentially affected (Tables 59.1 and 59.2).^{26,27} Initial symptoms are usually nonspecific, such as fever, cough, malaise, weight loss, night sweats, myalgias, and arthralgias. Signs of vascular deficiency develop later in the disease course and are most frequently ischemic in nature. Geographical variations in disease pattern have been reported, likely reflecting the interplay between host risk genes and this inflammatory vasculopathy. In North American, Japanese, and Korean patient populations, the aortic arch and its primary cervical and upper-extremity

branches are preferentially targeted, giving rise to aortic insufficiency, cerebral ischemia, face and neck pain, ocular ischemia, and the typical presentation of 'pulseless disease' (Fig. 59.6). In India, the abdominal aorta and renal arteries are more commonly affected, causing renovascular hypertension and the long-term risk of cardiac failure (Fig. 59.7).²⁸

Nonspecific complaints of headaches, syncope, and face and neck pain are often misinterpreted as stress-related problems, particularly in young women. Consequently, the diagnosis may be missed for months. Only few patients come to clinical attention with catastrophic neurological symptoms related to brain ischemia. Helpful clues are differences in blood pressure, loss of pulses, and vascular bruits heard on clinical examination. Retinal neoangiogenesis, induced by hypoperfusion of the eye, is now relatively rare, but fleeting visual abnormalities may indicate transient ischemic attacks. Signs of aortic insufficiency are unlikely to be encountered in early disease, but continuous monitoring for aortic dilation is part of follow-up care. Coronary artery stenosis in a young patient must prompt the physician to rule out TA. In a subset of patients, the origins of mesenteric arteries are involved by stenosing vasculitis. Clinical consequences include weight loss, nausea, vomiting, diarrhea, and abdominal claudication, typically elicited by the increased intestinal blood demand following a meal.

Renal artery stenosis may be clinically silent and is often noticed in routine screening. Correct measurement of blood pressures can represent a pressing clinical problem if the upper-extremity arteries are affected. Involvement of the infrarenal aorta may lead to lower-extremity claudication. Musculoskeletal examinations are usually unrevealing, although joint and muscle pains are common complaints.

DIAGNOSIS

Classification criteria have been developed for GCA and TA in order to differentiate patients with large-vessel vasculitis from those with other vasculitic entities (Tables 59.3–59.5).^{29–31} Age at disease onset and the pattern of arteritis are clearly important for establishing the diagnosis and

Fig. 59.6 Diagnosis of vascular involvement of Takayasu arteritis by chest computed tomography angiography. Axial images show marked thickening of the circumferential wall of both common carotid arteries (arrows). The vessel lumen is patent without evidence for hemodynamic stenosis. Lumen and wall of the vertebral arteries are normal.

Fig. 59.7 Magnetic resonance angiography of Takayasu arteritis. The three-dimensional reconstruction shows normal caliber of the ascending and descending aorta in a 16-year-old female with Takayasu arteritis. The infrarenal abdominal aorta is narrowed diffusely over a 7-cm segment. Here the lumen measures only 5 mm. Mild narrowing of the common iliac arteries bilaterally, just distal to the aortic bifurcation.

distinguishing between these two related vasculopathies. Diagnostic criteria for PMR remain a challenge (Table 59.3) as they rely on nonspecific symptoms, such as muscle pain and stiffness and elevated erythrocyte sedimentation rate (ESR), all of which can occur in many diseases.² No pathogenic test is currently available to diagnose PMR. Therapeutic responsiveness of PMR patients to low-dose corticosteroids continues to be clinically helpful but stresses the need for objective diagnostic criteria.

LABORATORY TESTS

In all three conditions, GCA, PMR, and TA, the vast majority of patients have laboratory findings of an intense acute-phase response.^{2, 23, 26} Generally, this is captured by measuring ESR or C-reactive protein (CRP). It is important to note, however, that a subset of GCA patients has normal ESR readings, even before initiation of immunosuppressive therapy. A normal ESR or CRP reading is not sufficient to exclude the diagnosis, and further diagnostic workup is required if clinical presentation is suspicious for vasculitis. Other acute-phase proteins, such as fibrinogen and serum amyloid A, have been reported to be elevated as well. The cytokine IL-6 is a potent inducer of acute-phase proteins in the liver and, being located upstream of ESR and CRP, has been found to be a sensitive marker of continuous systemic inflammation.³² Other laboratory abnormalities, such as elevation of alkaline phosphatase, thrombocytosis, and anemia, are in line with a robust acute-phase response.

Autoantibody measurements are not helpful beyond excluding differential diagnoses, such as rheumatoid arthritis, systemic lupus erythematosus, or anti-neutrophil cytoplasmic antibody (ANCA)-related vasculitides. No disease-specific autoantibodies for GCA and TA have been described, emphasizing that B cells are not involved in the pathogenic events leading to granulomatous inflammation of large vessels.

TISSUE BIOPSY

In patients with TA, tissue biopsies are rarely available unless the patient had to undergo vascular reconstructive surgery. In most patients, the diagnosis is made based on imaging procedures revealing luminal and wall abnormalities in affected blood vessels.

In contrast, arterial biopsy remains a critical diagnostic approach in patients with GCA. Temporal arteries are easily accessible, and a segment of these arteries can be removed in an outpatient setting. Recommendations include harvesting 2–3 cm of the temporal artery, starting at the most symptomatic side. Frozen tissue sections can lead to a quick diagnosis of granulomatous vasculitis. Whether the second side should be biopsied during the same surgical procedure remains a matter of debate. In cohorts including several hundred patients, vasculitis was detected in 2–3% of tissue samples from the second side if the first side was negative. If the clinical suspicion is strong, biopsy confirmation may be sought from a second-side biopsy immediately after the first biopsy or after

Table 59.3 American College of Rheumatology 1990 classification criteria for giant-cell arteritis^a and polymyalgia rheumatica

Age at disease onset ≥ 50 years
 New onset or new type of headache
 Temporal artery tenderness or decreased artery pulse
 Elevated erythrocyte sedimentation rate (≥ 50 mm/hour)
 Histologic incidence of arteritis
 (characterized by a predominance of mononuclear cell infiltrates or a granulomatous process with multinucleated giant cells)

(Reprinted from Hunder GG, Bloch DA, Michel BA, et al. The American College of Rheumatology 1990 criteria for the classification of giant cell arteritis. *Arthritis Rheum* 1990; 33: 1122–1128, with permission of Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc. ©1990.)

^aA patient is classified as having giant-cell arteritis if at least three of the five criteria are present.

careful monitoring of the patient several weeks later. Negative findings on temporal artery biopsy do not exclude the diagnosis of GCA. In a retrospective cohort study, about half of all patients with subclavian GCA had no evidence of vasculitis in the temporal arteries, emphasizing that the disease may display clear preference for certain vascular territories.³³

Corticosteroid therapy does not eradicate pathologic findings of vascular wall infiltrates and biopsy can still be valuable in making the diagnosis in patients already on steroids.³⁴ Nevertheless, it is possible that treatment with steroids leads to a false-negative biopsy result in some patients.

Histomorphologic reports describe mononuclear cell infiltrates penetrating through all layers of the vessel wall (Fig. 59.8).¹ Since the disease process enters the vessel wall through the adventitia, this may be the only site of inflammation. The finding of isolated inflammatory cell clusters in the adventitia, although not diagnostic, should at least be considered as highly suspicious. Multinucleated giant cells may or may not be found. They have a tendency to lie along the internal elastic lamina, at the junction between the media and the intima. Media destruction is not unusual, but findings of fibrinoid necrosis should prompt a search for a different vasculitic entity. The vessel lumen is more or less compromised by hyperplastic intima formed from proliferating fibroblasts, smooth-muscle cells, and deposition of acid mucopolysaccharides.

Histology of TA is similar to that in GCA, making it difficult to dissect both syndromes in tissue samples derived from the aorta or its primary branches.³⁵ Lymphocytes and plasma cells accumulate around vasa vasorum. Marked wall thickening with inflammatory tissue extending into perivascular structures is typical for TA (Fig. 59.9). Destruction of elastic membranes is often extensive and combined with patchy areas of media necrosis. Weakening of the vessel wall may lead to aneurysm formation. Notably, inflammatory lesions can be arranged in a 'skipped' pattern with normal vessel wall segments alternating with stretches of intense destructive inflammation.

Physicians can be confronted with morphologic findings of granulomatous aortitis in patients undergoing aortic aneurysm repair without any prior diagnosis of vasculitis. Detailed workup of these patients is

necessary to identify those with undiagnosed PMR, GCA, or TA. Rare causes of aortitis, including inflammatory bowel disease, sarcoidosis, syphilis, and connective tissue disease, should be ruled out. Isolated granulomatous aortitis is diagnosed as idiopathic aortitis. The pathogenesis and prognosis of this condition are essentially unknown, but relatively good outcomes have been described in patients who did not receive anti-inflammatory therapy.

DIAGNOSTIC IMAGING

Applying modern imaging modalities to the diagnosis and management of large-vessel vasculitis has been a major advance in caring for these patients.²³ Indeed, diagnosing TA mostly depends on identifying vascular lesions in typical distribution by imaging.³⁶

Conventional angiography still has its place in presurgical planning and can be combined with intravascular interventions. It provides ideal visualization of the vascular lumen not only for large but also for medium-sized arteries such as the axillary and brachial arteries (Fig. 59.4). Ultrasound (US)-based methods are extremely useful for screening carotid arteries but also emerge as the method of choice for initial assessment of the distal subclavian arteries, vertebral arteries, renal arteries, and femoral arteries. Also, US examination is the optimal method for long-term monitoring of vessel bypasses in patients who received surgical reconstruction. With its sensitivity to submillimeter changes and its noninvasiveness, US is gaining a dominant role as a diagnostic tool in the management of vasculitis.

Magnetic resonance (MR) imaging and MR angiography, as well as computed tomography (CT), are now widely used for evaluating the vascular tree. Both methods provide excellent information on abnormalities of the vascular lumen and wall, but are still limited to larger vessels and provide insufficient information about the distal subclavian arteries or the 2nd to 5th branches of the aorta. CT imaging is fast, well tolerated by claustrophobic patients, and allows excellent assessment of the aorta and its wall (Fig. 59.6). However, it has the disadvantages of contrast loading and radiation exposure. With its inherent multiplanar imaging capabilities, MR is used to examine neck vessels, the aorta, and its primary branches (Figs 59.5 and 59.7). Great hope was placed on its potential to measure wall edema and intramural vascularity, which would make MR a useful tool in estimating disease burden and responses to therapy. However, a carefully conducted study comparing imaging results with laboratory parameters of inflammation to results from surgically harvested vessel biopsies has been disappointing, cautioning that edema-weighted MR should not be used as a sole means of measuring disease activity and therapeutic responsiveness.³⁷

THERAPEUTIC MANAGEMENT

With increasing knowledge of the disease process and refinement of diagnosis and long-term treatment, the prognosis for large-vessel vasculitis patients has significantly improved. Life expectancy of patients with GCA is not shorter than of age-matched controls. Follow-up studies of Japanese patients with TA suggest good control of disease activity in about 75% of patients, with only 25% experiencing serious complications and cardiac manifestations that dominate long-term outcome. Recent discussions have focused on the question of whether vasculitis

Fig. 59.8 Histomorphology of giant-cell arteritis. **(A)** Temporal artery cross-section with mononuclear infiltrates throughout all wall layers. The adventitia is infiltrated by round cells with cuffing of vasa vasorum by lymphocytes. The vessel lumen is occluded by intimal hyperplasia. **(B)** Higher magnification showing intense granulomatous inflammation with multinucleated giant cells in the proximal media and at the media-intima junction.

predisposes patients to accelerated atherosclerotic disease, given the combination of chronic inflammation and injury to vessel wall structures. It is not known whether progression of atherosclerosis and its complications require a different management approach or whether standard vasoprotective measures (such as treating hypertension and hyperlipidemia and advising patients to avoid smoking) are sufficient.⁵

Pathogenic studies have pointed out that the traditional view of GCA as a self-limiting disease is incorrect.³³ To the contrary, granulomatous vasculitis has shown surprising resistance to immunosuppression in models of the disease, such as the temporal artery-SCID chimeras.³⁸ The paradigm of GCA as a chronic smoldering condition is supported by studies showing that sensitive markers of systemic inflammation remain

Fig. 59.9 Histopathology of Takayasu arteritis. **(A)** Full-thickness section of the aortic wall shows dense mononuclear infiltrates in the adventitia and media. The intima is thickened and wavy; hematoxylin and eosin (H&E). **(B)** Florid granulomatous inflammation along the media-intima junction with numerous giant cells; H&E.

elevated even in patients who are clinically asymptomatic and are weaned off immunosuppression. It is currently unknown whether this persistent smoldering disease process needs to be treated. Unchanged life expectancy in this population of elderly patients with an average age of 75 years at disease onset suggests that current management is adequate. It could be argued that intensification of immunosuppressive therapy is necessary to prevent long-term complications, such as aortic aneurysm/dissection from GCA aortitis. However, the number of patients developing such complications is low, and no evidence has been provided so far to indicate that therapy can stop progression of aortic wall destruction. The ultimate

Table 59.4 Diagnostic criteria for polymyalgia rheumatica

Age at disease onset ≥ 50 years
 Pain persisting for ≥ 1 month and involving two of these areas:
 neck, shoulders, and pelvic girdle
 Morning stiffness lasting > 1 hour
 Elevated erythrocyte sedimentation rate (> 40 mm/hour)
 Rapid response to prednisone (≤ 20 mg/day)
 Absence of other diseases capable of causing the
 musculoskeletal symptoms

THERAPEUTIC PRINCIPLES

- >> To prevent vision loss, patients with giant-cell arteritis (GCA) require immediate treatment. Similarly, with the threat of catastrophic cerebral ischemia in Takayasu arteritis (TA), prompt initiation of therapy is imperative
- >> Corticosteroids are the immunosuppressive drug of choice for large-vessel vasculitis. Often, they have to be given over a prolonged period of several years but may be clinically effective at very low doses
- >> Clinical trials have failed to show steroid-sparing effects for either methotrexate or antitumor necrosis factor- α therapy in patients with GCA
- >> Clinical experience (not evidence-based therapeutic trials) suggests that a combination of methotrexate, mycophenolate mofetil, or tumor necrosis factor- α -blocking agents with corticosteroids may be beneficial in disease control in some patients with TA
- >> Close monitoring for diabetes, hypertension, and hyperlipidemia combined with bone-saving therapy should be part of the treatment regime in patients with large-vessel vasculitis on long-term corticosteroids
- >> It is currently unknown whether the smoldering disease activity persisting beyond the acute phase of disease requires immunosuppressive therapy and whether the benefits of chronic immunosuppressive therapy outweigh the potential risks

decision depends on the cost–benefit analysis comparing the risk from smoldering disease with the risks imposed by long-standing immunosuppression.

The immunosuppressants of choice in GCA, TA, and PMR are corticosteroids. Notably, modern anti-cytokine reagents have failed to show therapeutic efficacy in GCA and PMR; however, they may have a place for a subset of TA patients.³⁹ Also, methotrexate, an anti-folate widely

used in rheumatology to suppress chronic autoimmune inflammation, appears to lack steroid-sparing action in GCA and PMR,⁴⁰ but may have a limited effect in TA.³⁹ The unparalleled response pattern of patients with large-vessel vasculitis to corticosteroids emphasizes disease-specific pathogenic pathways in these syndromes that are distinct from most other autoimmune entities. Equally remarkable is the fact that patients with GCA, PMR, and TA improve within hours after being started on steroid therapy. The response is usually dramatic, with improvements within 24–48 hours. The promptness of clinical improvement is so exceptional that it has been suggested as a diagnostic criterion for PMR. Much of the acute clinical benefit must relate to suppression of the systemic inflammatory syndrome. Signs and symptoms of vascular stenosis are much less responsive. Reduction in wall edema may help to re-establish some blood flow. Over time, formation of collateral blood vessels is an important mechanism for dealing with tissue ischemia.

Patients with GCA are started on a daily prednisone dose of 40–60 mg (about 1 mg/kg body weight). Once stabilized, steroid tapering is guided by close monitoring of the clinical presentation as well as laboratory markers of inflammation. In general, steroids should be reduced 10–20% every 2 weeks. Monthly monitoring of ESR and CRP is mandatory to adjust therapy. Patients frequently return with signs or symptoms of recurrent disease as immunosuppression is lowered. Fortunately, disease exacerbations causing vision loss are infrequent. Disease flares typically present with PMR symptoms or nonspecific manifestations of malaise and failure to thrive. In most patients, disease control can be reinstated by a transient small increase in the steroid dose.

A recent study has suggested that initial treatment of vasculitis may alter the patient's long-term course. Guided by experiments in human artery-SCID chimeras, patients with biopsy-proven GCA were treated with pulse corticosteroids as induction therapy.⁴¹ After receiving pulses of 1000 mg methylprednisolone for three consecutive days, therapy was continued on oral prednisone, and daily doses were swiftly tapered. Compared to patients in the control arm of the study, those who received the three initial steroid pulses had lower likelihoods of disease flares. Particularly, once they reached steroid doses close to 10 mg/day, these patients could tolerate steroid withdrawal significantly better, and the majority were taking 5 mg/day prednisone at 36 weeks.⁴¹ The benefit from initial pulse therapy continued over subsequent months of managing these patients. This study suggests that intense immunosuppression during early disease may be more effective in disrupting underlying immune abnormalities, thereby shortening the overall course of disease duration.

When given to human artery-SCID chimeras, acetylsalicylic acid (aspirin) has marked anti-inflammatory activities with suppression of the key cytokine interferon- γ in vascular lesions.⁴² Clinical trials are needed to test whether this immunosuppressive action can translate into corticosteroid sparing. Given that arteries are the primary target of large-vessel vasculitis, the use of aspirin as an anti-platelet agent should be routinely recommended.

There is no evidence that other immunosuppressants such as azathioprine and cyclophosphamide reduce the need for prednisone, prevent vascular complications, or shorten the duration of corticosteroid use.

An integral part of chronic immunosuppression with prednisone is regular monitoring for diabetes and hypertension. Patients should be encouraged to increase physical activity, as steroid-induced myopathy is a frequent finding in this population. A major issue of chronic steroid

Table 59.5 American College of Rheumatology 1990 criteria^a for the classification of Takayasu arteritis

Disease onset at ≤ 40 years
 Claudication of an extremity
 Decreased brachial artery pulse
 > 10 mmHg difference in systolic blood pressure between arms
 Bruit over the subclavian arteries or the aorta
 Arteriographic evidence of narrowing or occlusion of the entire aorta, its primary branches, or large arteries in the proximal upper or lower extremities

(Reprinted from Arend WP, Michel BA, Bloch DA, et al. The American College of Rheumatology 1990 criteria for the classification of Takayasu arteritis. *Arthritis Rheum* 1990; 33: 1129–1134, with permission of Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc. ©1990.)

^aFor purposes of classification, a patient is classified as having Takayasu arteritis if more than three of the six criteria are fulfilled.

treatment, particularly in elderly individuals, is the potential of excessive bone loss, possibly as a result of both increased bone resorption and impaired bone formation. A number of effective and safe therapies for osteoporosis are currently available. Obviously, calcium and vitamin D supplementation should be part of the therapeutic regimen.

Most patients can be discontinued from immunosuppressive treatment 18–24 months after diagnosis. Markers of systemic inflammation may remain elevated, and continuous monitoring for aortic involvement and recurrence of cranial arteritis is recommended.

In patients with PMR who have no evidence for frank vasculitis, much lower doses of steroids are necessary to induce prompt relief of symptoms. Most patients are sufficiently treated with an initial dose of 20 mg of prednisone per day. In some patients, 10 mg of prednisone can induce and sustain a clinical response. Physicians should aim at titrating steroids to minimally needed doses to avoid side effects; tapering usually needs to be slow, over many months.

In TA, initial therapy is similar to that in GCA, but long-term management needs to be tailored to individual patient conditions.³⁹ It has been discussed that patients should be maintained on a low dose of corticosteroids, such as 5–7 mg prednisone daily, even after successful control of active disease. Given the age at disease onset in TA, preventive measures to counteract accelerated atherosclerosis and optimize blood pressure control are important aspects of management.

It has been suggested that up to 50% of TA patients may require a second immunosuppressive agent.³⁹ Steroid-sparing effects of methotrexate have been reported for some patients. Similarly, mycophenolate mofetil may have clinical efficiency, although published data are only available on a small patient cohort. Finally, there may be a place for agents blocking tumor necrosis factor- α in patients with persistent disease activity. The dilemma is that well-designed placebo-controlled treatment trials testing the efficiency of such immunosuppressive drugs are lacking, mostly due to the infrequency of TA.

Detecting and treating hypertension is an essential component of caring for patients with TA. Untreated hypertension leads to acceleration of atherosclerosis and cardiac insufficiency. In patients

with upper-extremity involvement, obtaining accurate blood pressure measurements is a challenge and requires education of the patient and caregivers.

Besides pharmacologic therapy, revascularization procedures – including both surgical and endovascular interventions – have vastly broadened therapeutic options in patients with TA and large-vessel GCA.³⁹ To minimize the risk of complications, such as rapid reocclusion, an effort has to be made to suppress vascular wall inflammation optimally before subjecting the patients to revascularization treatment. Conventional bypass grafts are still considered the method of choice. Percutaneous transluminal angioplasty can be useful in managing renal artery stenosis or other short-segment lesions. Bypass surgery is needed in patients with cerebrovascular ischemia in whom catastrophic strokes may be prevented by bypassing critical stenosis of cervical vessels with grafts originating from the aortic arch. Re-establishing flow in upper- and lower-extremity arteries can be complicated by multiple and long-segment stenosis, and arterial reconstructions with prosthetic graft materials or vein may be the only alternative to obtain long-term patency. Placing of conventional stents may be complicated by eliciting rapid restenosis, and it is not known whether outcomes can be improved by drug-eluting stents. Occlusive disease of the coronary arteries usually represents a challenging clinical scenario, and most physicians opt for conventional bypass surgery. Depending on symptoms, patients with aortic regurgitation may require repair of the weakened aortic wall.

Autoinflammatory fever syndromes

60

Jeroen C. H. van der Hilst, Jos W.M. van der Meer,
Joost P.H. Drenth

Autoinflammatory syndromes, also known as hereditary periodic fever syndromes, encompass a group of genetic disorders characterized by lifelong recurrent febrile attacks of noninfectious origin. Each syndrome is characterized by a typical mix of symptoms that may include abdominal symptoms, arthralgias, arthritis, lymphadenopathy, and skin manifestations. Attacks of fever are always accompanied by an intense acute-phase response with elevated C-reactive protein (CRP), serum amyloid A (SAA), and leukocytosis.¹

Autoinflammatory syndromes can be distinguished from autoimmune diseases on several grounds. First, periodic fever is not a typical feature of autoimmune disorders. Moreover, several serological and cellular parameters such as the presence of autoantibodies or antigen-specific T cells do not play a role in the pathogenesis of autoinflammatory syndromes. In recent years, important steps have been made in understanding the pathogenesis of the autoinflammatory syndromes.

Without exception, autoinflammatory syndromes are disorders with a clear mendelian inheritance pattern. The progress in molecular genetics over the last decade has allowed the discovery of the genes implicated in a number of autoinflammatory disorders. The discovery of these genes and the corresponding proteins led to the identification of a new family of inflammatory proteins and their scaffold (named the inflammasome) that have a role in innate immunity. Recent research efforts have broadened the understanding of the mechanism of inflammation. Collectively this group of syndromes can be regarded as gain-of-function disorders in which the causative mutations lead to inappropriate and increased secretion of inflammatory cytokines, such as interleukin (IL)-1 β . In turn, this has led to the development of effective treatment strategies for these rare syndromes. This chapter describes the clinical pathology of six autoinflammatory disorders (Table 60.1).

The cornerstone of the diagnosis of the autoinflammatory diseases is clinical assessment. This includes a detailed medical and family history and clinical observation of an attack. Based on age of onset of symptoms, family history, ethnic background, accompanying symptoms, and duration of fever, most autoinflammatory syndromes can be differentiated on clinical grounds (Table 60.2).

Despite the fact that clinical assessment allows the identification of a number of syndromes, we fail to make a classifiable diagnosis in the

majority of patients who consult us with periodic fever. It is therefore to be expected that study of the pathogenesis of the various autoinflammatory syndromes will identify new proteins and pathways implicated in hitherto unrecognized syndromes.

■ EPIDEMIOLOGY ■

It is important to realize that autoinflammatory diseases are rare and that the incidence of the different autoinflammatory syndromes depends on the background population as the gene distribution depends to some extent on ethnicity. Without doubt, familial Mediterranean fever (FMF) is the most prevalent of these diseases, with more than 10 000 persons affected worldwide. It is found in persons originating from the Mediterranean basin, including Turks, Jews (primarily non-Ashkenazi), Armenians, and Arabs. However, sporadic cases in other ethnic groups have been described. With

Table 60.1 The autoinflammatory syndromes: names and acronyms

Name	Acronym
Familial Mediterranean fever	FMF
Hyperimmunoglobulin D and periodic fever syndrome	HIDS
Tumor necrosis factor receptor-associated periodic syndrome	TRAPS
Familial cold autoinflammatory syndrome	FCAS
Muckle-Wells syndrome	MWS
Neonatal-onset multisystemic inflammatory disease (also known as chronic infantile neurologic cutaneous and articular syndrome)	NOMID/CINCA
Cryopyrin-associated periodic syndrome	CAPS

Table 60.2 Autoinflammatory fever syndromes

	FMF	TRAPS	MWS	FCAS	NOMID	HIDS
Mode of inheritance	Autosomal recessive	Autosomal dominant	Autosomal dominant	Autosomal dominant	Autosomal dominant	Autosomal recessive
Age of onset (years)	< 20	Variable: most < 10	< 20	< 1	< 1	< 1
Main ethnic distribution	Turks, Arabs, Jews, Armenians	All races	European	European	European	Dutch, French
Gene involved	<i>MEFV</i>	<i>TNFRSF1A</i>	<i>CIAS1</i>	<i>CIAS1</i>	<i>CIAS1</i>	<i>MVK</i>
Duration of typical attack	12 hours–3 day	3 days–weeks	1–2 days	< 24 hours	?	4–6 days
Distinguishing symptoms	Pleural effusion, erysipelas-like skin lesion	Severe myalgia, periorbital edema	Sensorineural deafness	Induction by cold exposure	Epiphysian bone lesions, dysmorphic features	Cervical lymphadenopathy
Risk of amyloidosis*	Up to 75%	25%	33%	Unknown	Unknown	< 2%
Treatment	Colchicine	Etanercept, anakinra	Anakinra	Anakinra	Anakinra, corticosteroids	Simvastatin, anakinra

FCAS, familial cold autoinflammatory syndrome; FMF, familial Mediterranean fever; HIDS, hyperimmunoglobulin D and periodic fever syndrome; MWS, Muckle–Wells syndrome; NOMID, neonatal-onset multisystemic inflammatory disease; TRAPS, tumor necrosis factor (TNF) receptor-associated periodic syndrome.
*In patients that do not receive appropriate treatment.

the discovery of the incriminated gene, the MEditerranean FeVer gene (*MEFV*), it was appreciated that FMF is also relatively common in Italians and Ashkenazi Jews, although often with a less severe phenotype than in the high-prevalence populations. In selected populations, the carrier frequency can be as high as 1 in 3 to 1 in 5.² The high carrier rate suggests that carriers of the *MEFV* gene in the founder population may have had an evolutionary selection advantage, possibly due to protection against an infectious agent by an exaggerated inflammatory response.

The first patients with hyperimmunoglobulin D and periodic fever syndrome (HIDS) were described in 1984 in the Netherlands.³ So far, over 200 patients have been reported in a central registry (www.HIDS.net). The majority of patients come from western Europe, particularly the Netherlands and France. This observation is partly explained by the increased awareness among pediatricians in these countries, but also a founder effect has been described for the most prevalent mutation.⁴ Two mutations in the mevalonate kinase gene (V377I and I268T) account for almost 90% of the patients described to date.^{5,6} Almost all patients are of Caucasian origin, though cases from India and Japan have been described. Men and women are equally affected.

Tumor necrosis factor (TNF) receptor-associated periodic syndrome (TRAPS) was originally named familial Hibernian fever after the first family described, a Scottish–Irish family with periodic fever. Though TRAPS has been reported in families from Central America, Australia, and Central Europe, most families originate from north-western Europe. So far, a few dozen families and over 200 sporadic cases have been reported.^{7,8}

The cryopyrin-associated syndromes are all very rare. The exact prevalence is unknown: this can be explained by a lack of a central registry. In

addition, the genotype–phenotype relation is not always clear, which may leave many patients undiagnosed. In each of the three syndromes fewer than 200 cases have been reported in the literature, most often from European families.

■ PATHOGENESIS ■

FAMILIAL MEDITERRANEAN FEVER

The *MEFV* gene responsible for FMF was discovered in 1997 by two international collaborative groups and is located on the short arm of chromosome 16. So far, more than 70 mutations have been reported in a central registry (www.fmf.igh.cnrs.fr/infevers), most of which are clustered in exon 10 of the gene. The six most prevalent mutations (M694V, V726A, M680I, M694I, V694I, E148Q) represent some 80% of all cases.

The gene encodes a 781-amino-acid protein termed pyrin that is primarily expressed in neutrophils, macrophages, and eosinophils, but not in lymphocytes. Pyrin is a cytosolic protein and its expression is upregulated during myeloid differentiation. Several proinflammatory cytokines upregulate transcription of the *MEFV* gene.⁹

Pyrin is the first of a new class of proteins discovered that play an important role in the regulation of inflammation and apoptosis.¹⁰ These PYrin Domain (PYD)-containing proteins are a subfamily of the Death Domain (DD) superfamily. More than 20 different PYD-containing proteins have been described. The PYD domain of pyrin can bind to the PYD domain of other proteins like the apoptosis-associated speck-like

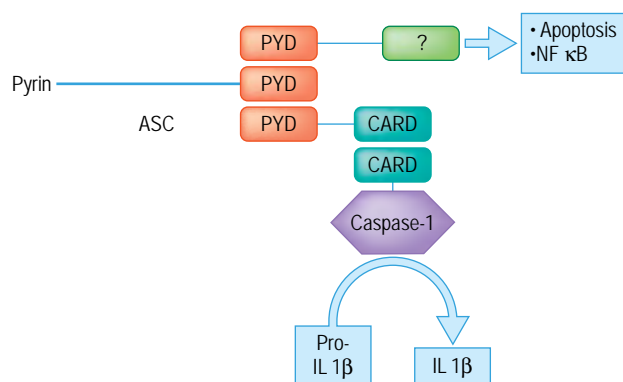

Fig. 60.1 Inflammatory mechanism of pyrin. Pyrin contains a PYD domain that can bind to apoptosis-associated speck-like protein (ASC). ASC in turn, can recruit caspase-1 via the CARD domain. Caspase-1 is capable of cleaving inactive proIL-1 β into active IL-1 β .

protein (ASC), forming complexes that activate caspase-1 to produce IL-1 β . Possibly, pyrin can also bind to other PYD proteins that can initiate apoptosis or activate NF- κ B (Fig. 60.1).

CRYOPYRIN-ASSOCIATED PERIODIC SYNDROME

The incriminated gene in cryopyrin-associated periodic syndrome (CAPS) encodes another member of the PYD protein family alternatively called cryopyrin, NALP3 and PYPAF1.¹¹ Cryopyrin is predominantly expressed in monocytes and granulocytes. Cryopyrin contains three domains: a pyrin domain (PYD), a nucleoside oligomerization domain (NOD), and a domain of leucine-rich repeats (LRR).¹⁰ Cryopyrin is able to associate with other proteins to form a complex termed the inflammasome. The central component of the inflammasome is a member of the NALP family (in case of the cryopyrin inflammasome: cryopyrin). It associates with the adaptor protein ASC, which in turn recruits proinflammatory caspase precursors (such as procaspase-1) (Fig. 60.2). The conversion of procaspase-1 into caspase-1 leads to the conversion of pro-IL-1 β into IL-1 β .¹² IL-1 β is a key mediator of inflammation, with a wide variety of effects ranging from induction of fever and extravasation of leukocytes to enhanced expression of adhesion molecules on endothelial cells and induction of bone resorption.

TUMOR NECROSIS FACTOR RECEPTOR-ASSOCIATED PERIODIC SYNDROME

TRAPS is caused by mutations in *TNFRSF1A*, located on chromosome 12p13. The gene encodes TNF receptor superfamily 1A (TNFRSF1A), the main surface receptor for TNF.¹³ TNFRSF1A has three important domains: an extracellular ligand-binding domain, a transmembrane portion, and an intracellular effector domain (DD) belonging to the DD superfamily. More than 50 different *TNFRSF1A* mutations have been described that cause TRAPS. The TRAPS-associated mutations are all located within the extracellular domain of the molecule. The TNF receptor forms trimers after binding to its ligand. Upon binding of TNF, the intracellular DD recruits TRADD. TRADD is able to recruit other molecules to initiate a downstream signaling cascade leading

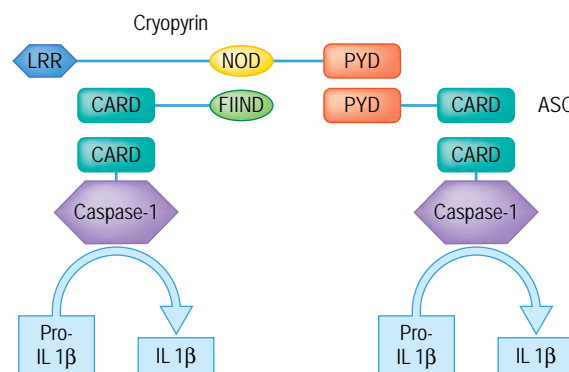

Fig. 60.2 The cryopyrin inflammasome. Cryopyrin is the central component of the cryopyrin inflammasome. Cryopyrin contains three domains: a pyrin domain (PYD), a nucleoside oligomerization domain (NOD), and a domain of leucine-rich repeats (LRR). Cryopyrin binds ASC through its PYD domain and through the NOD domain. The association of these proteins ultimately leads to the release of active caspase-1, which in turn activates IL-1 β through the cleavage of proIL-1 β . Upon its secretion into the extracellular milieu, IL-1 β sets off a series of events that result in inflammation.

to NF- κ B activation and caspase-induced apoptosis (Fig. 60.3). Furthermore, upon receptor activation through TNF, the extracellular domain of the TNF receptor is shed from the membrane. This shedding of receptors leads to a pool of soluble TNF receptors that is thought to mitigate the immune response.

Two hypotheses are offered to explain the inflammatory phenotype of TRAPS. The *shedding hypothesis* was first coined after the initial observation that patients with TRAPS have reduced serum levels of soluble TNF receptors. Furthermore, *in vitro* experiments showed that some mutated cell lines exhibit impaired shedding of TNF receptors.¹³ The defective shedding would lead to a deficiency of soluble TNF receptors that can scavenge excess TNF and diminish the immune response. Furthermore, since receptors remain present on the membrane, there is ongoing stimulation of the cells. However, the shedding hypothesis fails to explain the complete phenotype, as not all TRAPS patients have defective shedding. Recently an alternative explanation, the so-called *misfolding hypothesis*, was proposed.^{14,15} Several mutations in the extracellular domain of TNFRSF1A lead to misfolding of the molecule. The misfolded receptors are not expressed at the surface, but are retained intracellularly. *In vitro* results show that the aggregated TNFRSF1A retain signal function and can induce ligand-independent NF- κ B activation and apoptosis.

HYPERIMMUNOGLOBULIN D AND PERIODIC FEVER SYNDROME

HIDS is caused by mutations in the mevalonate kinase gene (*MVK*), located on the long arm of chromosome 12 (12q24). Mevalonate kinase is a key enzyme in the isoprenoid pathway and follows 3-hydroxy-3-methylglutaryl-coenzyme A reductase (HMG coA reductase). In patients with HIDS, the activity of mevalonate kinase is reduced to 5–15% of normal levels.⁵ In the isoprenoid pathway cholesterol is produced in

Fig. 60.3 Proposed pathophysiology of tumor necrosis factor receptor-associated periodic syndrome (TRAPS). (1) Tumor necrosis factor (TNF) binds to the TNF receptor on the surface of inflammatory cells (2). After receptor triggering, TRADD is recruited and a signal leads to apoptosis and cytokine production (3). In healthy individuals the receptors are shed from the surface, leading to a pool of receptors that dampen immune response (4). In patients with TRAPS there is diminished shedding, which may lead to a proinflammatory state by ongoing stimulation of retained cell surface receptors. Alternatively, the deficiency of soluble TNF receptors reduces scavenging of excess TNF. (5) Other research has shown that mutated TNF receptors form aggregates and are retained intracellularly. These aggregated receptors are capable of binding TRADD and stimulate ligand-independent cytokine production.

addition to a number of nonsterol isoprenoids. Isoprenoids are essential compounds in diverse cellular function and include ubiquinone, heme A, farnesyl, and geranyl. How a reduced activity of mevalonate kinase leads to an autoinflammatory condition is not known. It can be caused by a lack of isoprenoids or by an excess of the substrate of mevalonate-kinase: mevalonic acid. Proinflammatory cytokine production by mononuclear cells of patients with HIDS is strongly enhanced.¹⁶ Furthermore, a defect in apoptosis of HIDS lymphocytes has been detected.¹⁷ It has been hypothesized that this leads to an inability to curtail an excessive cytokine response after a trivial stimulus.

FAMILIAL MEDITERRANEAN FEVER

Clinical features

FMF is an autosomal recessive disease. Over 90% of patients become symptomatic within the first two decades of life. Typically an attack has an abrupt onset with high fever, reaching a peak soon after onset, lasting from 12 hours to 3 days and then rapidly subsiding.¹⁸ There are no consistent triggers, but in some patients vigorous exercise, emotional stress, or menstruation precedes an attack. The frequency of attacks varies

greatly between patients, from once every week to only once every few years. Even in a given patient the frequency can vary greatly. Signs of painful serositis accompanying the fever are the hallmark of the disease.

Abdominal pain of 1 or 2 days' duration occurs in > 95% of patients. The abdominal pain may originally be focal, and then progresses to become more generalized. It is caused by a sterile peritonitis with a major influx of neutrophils. Many patients have undergone exploratory abdominal surgery because of an acute abdomen, with the resection of an uninfamed appendix. Sometimes adhesions are seen, presumably the result of recurrent peritoneal inflammation. Pelvic adhesions can reduce fertility in female patients.

Other serosal and synovial membranes are often involved. Pleural inflammation presenting as unilateral pleural pain is experienced by ~40% of patients. Synovitis presenting as monoarthritis with effusion of the knee, ankle, or wrist occurs in half to three-quarters of patients. An arthritic attack may have a more protracted course, with fever lasting up to a week. The synovitis usually resolves completely without joint destruction. Pericarditis is rare (< 1%). Erysipelas-like skin lesions are reported in 7–40% of patients.¹⁹ The lesions mimic acute infectious cellulitis occurring on the lower extremities. Other less frequently encountered symptoms include vasculitis, such as polyarteritis nodosa and Henoch-Schönlein purpura, orchitis, aseptic meningitis, and myalgia. The literature is replete with genotype-phenotype studies, and the most consistent finding is that the M694V/M694V genotype carriers have earlier onset of symptoms and higher frequency of arthritis. The life expectancy of patients depends on receiving appropriate treatment to prevent amyloidosis (see related paragraphs).

Laboratory investigation

There is no specific biological marker for FMF. During attacks patients show a strong acute-phase response with high CRP concentrations and leukocytosis. During remission laboratory analysis shows signs of persistent inflammation despite the fact that patients are clinically well.²⁰ Proteinuria (more than 0.5 g of protein per 24 hours) in patients with FMF is highly suggestive of amyloidosis.

Diagnosis

FMF is a clinical diagnosis (Table 60.3). A set of validated diagnostic criteria has been designed at the Sheba Medical Center at Tel Hashomer in Tel Aviv, Israel.²¹ When applied in a population with high pretest probability, it has a high positive and negative predictive value. It is unknown whether these criteria can be applied to other populations with lower disease frequency. In general, when a patient has a typical medical history and stems from a high-prevalence ethnic group, the diagnosis is not difficult to make. FMF has been described in a wide variety of ethnic groups, so ancestry should not be used to rule out the diagnosis. In atypical cases and in patient from low-prevalence ethnic groups, genetic testing can be useful in the diagnostic process.

CRYOPYRIN-ASSOCIATED PERIODIC SYNDROME

Originally, CAPS was identified as three different syndromes with distinct clinical features. All types of CAPS are autosomal dominantly inherited. With the discovery of the incriminated gene there is increasing awareness that there are many patients with overlapping symptoms.²² Furthermore, a particular genetic mutation can result in different

Table 60.3 Criteria for the diagnosis of familial Mediterranean fever

Major criteria

- Typical attack^{*} with abdominal symptoms
- Typical attack with pleural symptoms
- Typical attack with monoarthritis
- Typical attack with only fever
- Incomplete attack[†] with abdominal symptoms

Minor criteria

- Favourable response to colchicine
- Incomplete attack with monoarthritis
- Exertional leg pain

^{*}Typical attacks are defined as at least three attacks with fever > 38°C.
[†]Incomplete attacks are painful and recurrent attacks not meeting the criteria for typical attack. The diagnosis of familial Mediterranean fever requires one major or two minor criteria. The sensitivity and specificity of these two criteria sets were > 95% and > 97%.²¹

phenotypes, suggesting the role of other disease-modifying genes. Though each of the cryopyrin-associated syndromes has distinctive clinical features, the common genetic basis and the many overlapping clinical manifestations support the notion of a continuous spectrum of diseases with different severities.

FAMILIAL COLD AUTOINFLAMMATORY SYNDROME

Clinical features

Familial cold autoinflammatory syndrome (FCAS) has an almost complete penetrance. The disease becomes clinically manifest in early childhood. In 60% of patients, the first symptoms develop within the first days of life. Symptoms typically occur after a few minutes to a maximum of 3 hours after being exposed to temperatures lower than 22°C. A recurrent characteristic rash is always present. The rash usually starts on the extremities and can extend to other parts of the body. It is described by patients as itchy or burning. Most attacks are accompanied by fever and chills, recurrent arthralgia, and conjunctivitis. Other commonly reported symptoms are profuse sweating, headache, extreme thirst, and nausea.²³ Attacks generally resolve spontaneously after a few hours to a day. Localized exposure to cold does not provoke an attack, which distinguishes it from acquired cold urticaria. Many patients with FCAS also show evidence of chronic inflammation between attacks, particularly a daily pattern of rash developing in the afternoon that can be associated with headaches, myalgia, and fatigue. The symptoms tend to become less severe with advancing age.

Laboratory investigation

The most consistent finding during attacks is a polymorphonuclear leukocytosis, with white blood cell counts up to 36 000/mm³. Erythrocyte sedimentation rate can be moderately elevated, as are other acute-phase

reactants. No cold agglutinins or cryoglobulins are present. Skin biopsies from the urticarial rash show neutrophil efflux.

Diagnosis

FCAS is diagnosed based on the typical clinical features in combination with a positive family history.²⁴ Genetic testing is available.

MUCKLE-WELLS SYNDROME

Clinical features

This autosomal dominant disorder was originally described by Muckle and Wells as a triad of urticaria, deafness, and amyloidosis in a large family. Patients with Muckle–Wells syndrome (MWS) have short bouts of inflammation (12–48 hours); sometimes the attacks are triggered by cold exposure, minor trauma, or emotional stress. The age of onset is variable and ranges from neonatal onset to adolescence. Inflammatory attacks are preceded or accompanied by an urticarial skin rash. The trunk and extremities are most frequently involved, more rarely the face. Arthralgias are a common feature of attacks and can be disabling. Sometimes they are accompanied by large-joint effusion. Arthralgias tend to subside when skeletal growth ceases. Other symptoms may include conjunctivitis, uveitis, severe fatigue, and aphthous ulcers.²⁵ A distinctive feature of MWS is sensorineural deafness. It has been reported to occur in about 70% of patients. The progressive loss of hearing usually starts in early childhood, but late onset of perceptive deafness is not uncommon.

Laboratory investigation

Leukocytosis and elevated acute-phase reactants are invariably present. Skin biopsies of the lesions show a polymorphonuclear infiltrate.

Diagnosis

Most patients have a positive family history, but isolated cases have been reported. The diagnosis is made on clinical grounds in combination with genetic testing. Genetic testing of rare disorders, such as MWS, is commercially available (www.genedx.com).

NEONATAL-ONSET MULTISYSTEM INFLAMMATORY DISEASE

Clinical features

Neonatal-onset multisystem inflammatory disease (NOMID) is an autosomal dominant inherited condition characterized by a triad of cutaneous, articular, and neurological symptoms. Patients have chronic inflammation with episodic bouts of fever and worsening of symptoms. NOMID has a much more severe clinical course than the other two cryopyrin-associated syndromes. Typically, patients are born prematurely and have a nonpruritic urticarial-like rash. Central nervous system manifestations include chronic aseptic meningitis, increased intracranial pressure, hydrocephalus, seizures, and sensorineural deafness.¹¹ Chronic papilledema with optic nerve atrophy can result in loss of vision. Headache caused by aseptic meningitis is a prominent

feature. Magnetic resonance studies from the brain show ventriculomegaly and mild-to-moderate cerebral atrophy. High-resolution images show arachnoid adhesions and cochlear enhancement. The central nervous system involvement often leads to mental retardation. Articular symptoms are a prominent feature of NOMID.²⁶ A highly characteristic arthropathy, with distinct radiographic findings of premature patellar and epiphyseal long bone ossification and resultant osseous overgrowth, develops early in life. It leads to short stature, severe contractures, and disability. It is unclear whether the bone manifestations are caused by IL-1 β -driven inflammation or result from impaired apoptosis of chondrocytes. The prognosis is grave, with a reported mortality rate of 20% before adulthood due to infection, vasculitis, and amyloidosis.

Laboratory investigations

Patients with NOMID have a continuous inflammation, with elevated SAA and CRP and elevated leukocyte counts. There is meningeal inflammation with increased protein concentrations and elevated white-cell counts in the cerebral spinal fluid.

Diagnosis

NOMID can be diagnosed based on characteristic clinical manifestations. Mutational analysis is available (www.genedix.com), but in some patients no mutations are found.

TUMOR NECROSIS FACTOR RECEPTOR-ASSOCIATED PERIODIC SYNDROME

Clinical features

TRAPS is inherited in an autosomal dominant manner. The age of onset varies widely, but most patients become symptomatic within the first few years of life. The median age of onset is 3 years. The usual duration of episodes in TRAPS is considerably longer than in the other autoinflammatory syndromes. An attack persists for a minimum of 3 days, but can last for weeks. The interval between attacks can vary substantially within a single patient. Localized myalgia affecting a limb associated with fever is found in virtually all patients.²⁷ Patients describe it as a deep cramping muscle pain, often severely disabling. The symptoms are probably due to a monocytic fasciitis. Cutaneous manifestations are present in the large majority of patients during attacks. They consist of localized erythematous macules and patches that tend to migrate to the distal part of the extremities.²⁸ Abdominal pain, often accompanied by vomiting, constipation, and bowel obstruction, occurs in almost all patients. Arthralgia and monoarticular arthritis involving hips, knees, and ankles are present in a quarter of patients at some point in the natural history of their disease. Chest pain is a frequent feature and may be either pleural in origin or reflect musculoskeletal involvement.

Characteristic ocular symptoms in TRAPS range from conjunctivitis and periorbital pain to severe uveitis and iritis. Periorbital edema with conjunctival injection is another distinctive but infrequent feature of TRAPS. Other less frequently observed symptoms are pericarditis, and inflammation of the tunica vaginalis, leading to scrotal pain. Lymphadenopathy is rare.

Laboratory investigations

During an attack of TRAPS laboratory investigations indicate an acute-phase response, with elevated erythrocyte sedimentation rate, CRP, haptoglobin, fibrinogen, and ferritin. A large proportion of patients also demonstrate an elevated acute-phase response between clinically symptomatic attacks. Complete blood count may demonstrate neutrophilia, thrombocytosis, and anemia of chronic disease. Polyclonal gammopathy as well as small monoclonal gammopathy occur. Autoantibodies, including antinuclear antibodies, anti-cardiolipin antibodies and rheumatoid factor are negative or are found at low titers.

Diagnosis (Table 60.4)

Hull et al. have proposed a set of diagnostic criteria for TRAPS.²⁷ However, these criteria have not been validated, and information about sensitivity and specificity of this diagnostic test is lacking. Genetic testing is the mainstay in the diagnosis of TRAPS.

HYPERIMMUNOGLOBULIN D AND PERIODIC FEVER SYNDROME

Clinical features

HIDS is an autosomal recessively inherited disease that was first recognized as a separate disease entity in 1984. Patients with HIDS have recurrent fever attacks of 4–6 days' duration that start in early childhood.¹⁶ The inflammatory attacks occur on average every 4–6 weeks, although there is considerable variation within a single patient and between patients. An attack begins with chills followed by a sharp rise in temperature. Factors known to provoke an attack are infection, trauma, vaccination, and both physical and emotional stress, although often a trigger is not obvious. Typically, parents recall the first attack of their child occurring after the first childhood vaccination. The febrile episodes are accompanied by cervical lymphadenopathy and abdominal pain with vomiting and diarrhea. Cutaneous manifestations of HIDS present primarily as erythematous macules and papules, urticaria, and different forms of rash and exanthema (Fig. 60.4). A minority of patients have painful oral and genital aphthous ulcers. Arthralgias and arthritis accompany attacks in nearly 70% of patients, involving the large joints in a polyarticular fashion. Synovial aspirates show a leukocyte-rich fluid

Table 60.4 Diagnostic indicators for tumor necrosis factor receptor-associated periodic syndrome

Recurrent episodes of inflammatory symptoms spanning a period of more than 6 months' duration. Inflammatory symptoms include fever, abdominal pain, myalgia, rash, conjunctivitis/periorbital oedema, chest pain, and arthralgia or monoarticular synovitis
Episodes lasting more than 5 days
Responsiveness to glucocorticosteroids, but not colchicine
Affected family members (not always present)
Any ethnicity may be affected

negative for bacterial growth. Other findings in HIDS are splenomegaly, hepatomegaly, and tendinitis. After 4–6 days there is gradual defervescence, leaving patients completely asymptomatic in between attacks. Patients with HIDS have a normal life expectancy. The frequency and severity of attacks tend to decrease later in life.

It should be noted that the genetic abnormality in HIDS – mevalonate kinase deficiency – is also present in a more severe disease: mevalonate aciduria. In this inborn error of metabolism there is also periodic fever, but the clinical picture is dominated by psychomotor retardation, ataxia, failure to thrive, cataract, and dysmorphic facies. Most patients die in early childhood.

Laboratory investigation

Laboratory evaluation at the time of attack reveals a vigorous acute-phase response with leukocytosis, raised serum concentrations of CRP, and proinflammatory cytokines such as IL-6, TNF- α , and interferon- γ . Even in between attacks, when patients are asymptomatic, half the patients have laboratory evidence of continuing inflammation. The principal laboratory finding is a persistent elevation of polyclonal immunoglobulin D (IgD). In 80% of patients this is accompanied by an elevation of IgA as well. IgD concentrations do not correlate with disease activity. The mechanism of elevation of IgD is unknown. During attacks traces of mevalonic acid in the plasma can be found, but the increase is only slight.

Diagnosis

The diagnosis of HIDS can be established by characteristic clinical findings in combination with persistent elevated IgD (> 100 IU/ml). Elevation of IgD is not pathognomonic as it also occurs in other inflammatory conditions, including FMF. Furthermore, in the very young, IgD levels can be normal, and in a small number of patients IgD levels remain

low. The diagnosis can be confirmed by DNA analysis; however, in almost half the patients with a periodic fever, elevated acute-phase response, and elevated IgD, no mutations in *MVK* are found. The latter group, which has been described as variant HIDS,⁹ suffers from less severe disease, usually with a later onset and IgD concentrations that are not as high as in classic HIDS.

AMYLOIDOSIS

Reactive or type AA amyloidosis is a serious complication of all autoinflammatory syndromes.²⁹ It is caused by the deposition of insoluble fibrils in the extracellular matrix of organs and tissues, most notable the kidneys, spleen, and liver. The fibrils are composed of a degradation product of SAA. Since SAA is an acute-phase reactant there is a close relationship between the continuous elevation of SAA and the development of amyloidosis. Before the recognition of colchicine as an effective treatment for FMF, amyloidosis occurred in up to 75% of patients. Even before the advent of effective treatment, not all FMF patients developed amyloidosis, suggesting that other factors contribute to the risk of developing amyloidosis.

In FMF there is a strong correlation between ethnicity and risk of amyloidosis, with the highest risk for Sephardic Jews. Another identified risk factor for developing amyloidosis is single nucleotide polymorphisms (SNPs) in the *SAA* gene. Two SNPs define three different SAA proteins: SAA 1.1, 1.3, and 1.5. Patients with the *SAA* 1.1/1.1 genotype have a three- to sevenfold increased risk of developing amyloidosis.³⁰

Up to a quarter of TRAPS patients develop amyloidosis. There seems to be a strong family predilection. In some families almost all adults are affected whereas in other families no cases of amyloidosis are found. Hopefully, with the recent progression in treatment, the number of new cases of amyloidosis will decrease in the near future.

Although MWS was originally described as a triad of deafness, urticaria, and amyloidosis, not all patients with MWS develop amyloidosis. Approximately one-third of patients develop amyloidosis, and there is familial clustering. Several cases have been described in FCAS and NOMID, but numbers are too small to make an accurate estimate of the prevalence.

Patients with HIDS have a relatively small risk of developing amyloidosis. In fact, only recently the first cases of amyloidosis were described. Still there is a remarkably lower incidence of amyloidosis in HIDS compared to the other periodic fever syndromes, despite a similar acute-phase response.

A diagnosis of amyloidosis is confirmed by Congo red staining of affected tissues, showing a typical apple-green birefringence under polarized light microscopy (Fig. 60.5). Biopsy of subcutaneous fat or rectal tissue can be used to detect amyloid fibrils. If these are negative and there is a high index of suspicion, a direct biopsy from an affected organ can be considered.

The prognosis of patients with established amyloidosis is grave, with a median survival of 24–53 months. The natural history of amyloidosis is progression to renal failure. If inflammation cannot be controlled, amyloid deposits in a variety of organs (liver, spleen, gastrointestinal tract, heart) occur. As a consequence malabsorption with severe diarrhea may ensue. Cardiac failure and rhythm disturbances are typical manifestations of cardiac involvement. The progression of amyloidosis is strongly dependent on the ability to control the underlying inflammatory process.

Fig. 60.4 Migrating erythematous macular rash during an inflammatory attack in a tumor necrosis factor receptor-associated periodic syndrome (TRAPS) patient.

Fig. 60.5 Tissue section of a renal biopsy from a patient with AA amyloidosis. Amyloid deposits are visualized by staining with Congo red (**A**). Under polarized light microscopy amyloid deposits shows typical apple-green birefringence (**B**).

If the SAA concentration can be kept under 10 mg/l, progression of amyloidosis can be halted in many cases, and in some the amyloid mass even slowly regresses.³¹

TREATMENT

COLCHICINE

Colchicine is the treatment of choice in FMF.³² It is highly effective in preventing attacks. In fact, it is so effective in preventing attacks that response to colchicine has been used as a clinical criterion for diagnosing FMF. The mechanism of action is unknown. Colchicine therapy is also very efficient in preventing amyloidosis. Therefore, all patients with FMF should receive colchicine, regardless of the severity and frequency of attacks. In patients who already have amyloidosis, intensive treatment can sometimes arrest progression or even partially reverse the process.

The average daily dose is 1 mg/day. In cases in which this is not sufficient to prevent attacks the dose can be increased to up to 3 mg. There is a small subset of patients who do not respond to colchicine. The most encountered side effect, gastrointestinal discomfort with diarrhea, usually resolves with dose reduction. Myopathy, neuropathy, and leukopenia are rare, but serious, side effects that primarily occur in patients with renal or liver impairment. In animal studies teratogenic effects are only seen at extremely high dosages. The potential teratogenic role of colchicine arises from its effect on microtubules, and there has been some concern that colchicine could therefore increase inborn errors, especially trisomy 21. However, recent data suggest that colchicine is safe to use during pregnancy. It can also be used while breastfeeding. In therapeutic dosages colchicine does not interfere with sperm quantity or quality. Furthermore, a clinical series of male patients on colchicine did not detect a negative effect on fertility. There is no place for colchicine in the treatment of autoinflammatory syndromes other than FMF.

SOLUBLE TNF RECEPTOR

The initial observation of reduced concentrations of soluble TNF receptors in the serum of TRAPS patients raised the possibility of etanercept as a therapeutic agent. Etanercept is a fusion protein consisting of two chains of the recombinant TNF- α receptor p75 monomers fused with the Fc domain of human IgG1. There are several reports of successful treatment with etanercept, although most patients do not have complete remission of symptoms. In TRAPS patients with established amyloidosis, etanercept can significantly reduce proteinuria. Etanercept has also been tried in HIDS with promising results in a small number of patients. The arthropathy in chronic infantile neurologic cutaneous and articular syndrome (CINCA) may respond to etanercept therapy.

ANAKINRA

Anakinra is a recombinant form of human IL-1Ra that competitively inhibits binding of IL-1 α and IL-1 β to the IL-1 receptor type 1. With the advances in the understanding of the genetic and molecular basis of the autoinflammatory syndromes, the concept emerged that IL-1 β plays a key role in inflammation, and the successful intervention with anakinra in these syndromes provides the best evidence for such a role of IL-1. Recently there has been a focus on the effects of anakinra in CAPS, TRAPS, and HIDS, and although preliminary, the results are very promising. In 2003, Hawkins and Lachman described a patient with MWS who had been unsuccessfully treated with an array of immunosuppressive drugs, but who had a virtual instant and complete response to anakinra.²⁵ These beneficial effects were confirmed in a larger study of 22 patients. Anakinra is well tolerated and gives a complete resolution of fever, rash, conjunctivitis, and joint symptoms. Furthermore, because of the suppression of acute-phase reactants it can probably prevent amyloidosis.

These favorable results triggered research in other cryopyrin-associated syndromes. In NOMID, a similar dramatic response was found in a clinical study of 18 patients.¹¹ The skin rash disappears within 24 hours of start

of treatment. Also, neurological symptoms resolve and in many patients hearing improves. Further, steroids can be tapered in the majority of patients. The follow-up has been too short to evaluate the effects of anakinra on prevention of bone deformities. FCAS also responds to anakinra treatment. In a well-designed provocation model, Hoffman et al. showed that anakinra effectively prevented attacks when given prior to cold stimulation.²³ In TRAPS no controlled trials are available, but there are reports in the literature indicating a similar improvement in symptoms.

Evidence is accumulating that blocking IL-1 β is effective in treatment in HIDS.³³ Anakinra can prevent attacks when given before a trigger, and it has been shown effective in reducing attacks in severe cases. On theoretical grounds, anakinra may be effective in FMF, but since colchicine is so effective, this option has not been studied to a great extent. In a patient with colchicine-resistant FMF we observed a clinical response to anakinra.

An unsettled question is in which way anakinra should be given. One option is chronic suppression of the inflammatory response by daily injections, and this is probably the best regimen in the cryopyrin-associated syndromes, where there is continuous inflammation. In HIDS and TRAPS it is less clear. Here, one may consider patient-initiated treatment at the first sign of an attack. It is unclear as yet how long treatment should be given under these circumstances. With continuous treatment with anakinra in TRAPS we have observed breakthrough attacks, of which the mechanisms are unclear. Under such circumstances we have been able to induce a remission for several weeks with a couple of intravenous injections of 300 mg of anakinra. The latter observation suggests that in patients who do not readily respond to anakinra, a higher dose (intravenously) should be considered.

CORTICOSTEROIDS

A course of steroids (30 mg daily for 1 week) can be used to treat attacks of TRAPS. Severe attacks may respond to high doses of corticosteroids, such as 1 g methylprednisolone infusion. Corticosteroids, however, while reducing the severity of symptoms, do not alter the frequency of attacks, and often escalating dosages are needed over time. In NOMID, corticosteroids can ameliorate skin manifestations and joint symptoms, but remission cannot usually be induced. Corticosteroid treatment is ineffective in FMF and HIDS.

SIMVASTATIN

The possibility that the inflammatory phenotype in HIDS is caused by an excess of mevalonic acid would make an inhibitor of the preceding enzyme, i.e., HMG-coA reductase inhibitors, a therapeutic option. A small controlled trial has demonstrated some advantage of simvastatin over placebo in terms of reduction of the number of days of illness, but the overall efficacy is limited.³⁴

OTHER IMMUNOSUPPRESSIVE DRUGS

Testament to the problems in treating the autoinflammatory diseases are the multiple therapeutic agents that have been tried. The often disabling features and the lack of therapeutic agents might lead to a trial-and-error practice exposing these patients to empirical treatment with an array of immunomodulating drugs, such as Cyclosporine, thalidomide, dapsone, azathioprine, mycophenol, and infliximab. Results are disappointing and there is no evidence to support the use of these agents.

CLINICAL PEARL

An 18-year-old woman was seen because of recurrences of fever and skin rash. Her medical history started 2 hours after birth when a maculopapular skin rash appeared, resembling the systemic rash of juvenile chronic arthritis. The rash remained present on a daily basis, but was not triggered or exacerbated by cold exposure. At the age of 2 years, the patient developed fever episodes, approximately 3 days per week. Typically, she had a single fever spike a day, usually in the evening, and body temperature was in the range of 39°C.

The patient is of European ancestry and the family history is negative for autoinflammatory conditions. Articular symptoms were absent, and she had a normal audiometry, while dysmorphic features, meningitis, myalgias, abdominal pain, and lymphadenopathy were absent.

Based on the clinical presentation (daily rash and spiking fever), a cryopyrin-associated periodic syndrome (CAPS) was suspected and targeted gene analysis performed. This showed an R260W mutation of the *CIAS1* gene. This mutation has been found in Muckle-Wells syndrome as well as in patients with familial cold autoinflammatory syndrome. Thus, the patient has a CAPS. However, since she has symptoms consistent with each of the three separate disease entities and lacks other distinguishing symptoms, the patient should not be classified in one of the three distinct syndromes. This illustrates that CAPS is a continuous spectrum of diseases that show great phenotypical overlap. After making the diagnosis the patient was successfully treated with anakinra.

CONCLUSION

The autoinflammatory syndromes are a still expanding group of disorders, characterized by incapacitating attacks of inflammation. In recent years, the genetic background, the molecular pathophysiology, the focus point of the inflammasome, and a key role for IL-1 have surfaced. These insights have provided us with tools for diagnosis and counseling and also for effective treatment. An important challenge is to find other – preferably orally effective – drugs that interfere with IL-1 action.

Although the autoinflammatory syndromes are rare, the study of these diseases has contributed to the insight into important mechanisms of inflammation in general. In the future, with advancing knowledge, we expect new syndromes to be discovered that can contribute to further insight into basic mechanisms of inflammation.

Antiphospholipid syndrome

Doruk Erkan, Michael D. Lockshin

61

Diagnosis of the antiphospholipid syndrome (APS) requires that a patient have *both* a clinical event (thrombosis or pregnancy loss) *and* persistent antiphospholipid antibody (aPL), documented by a solid-phase serum assay (anticardiolipin [aCL] or anti β_2 -glycoprotein-I [β_2 GPI] enzyme-linked immunosorbent assay) or by an inhibitor of phospholipid-dependent clotting (lupus anticoagulant [LA] test) or by both.¹ Table 61.1 displays the 2004 Sydney Revision¹ of the Preliminary Sapporo APS Classification Criteria.² Antiphospholipid syndrome occurs as an isolated diagnosis or associated with other systemic rheumatic diseases such as systemic lupus erythematosus (SLE).

The primary antigen to which aPL binds is β_2 GPI (apolipoprotein H), a phospholipid-binding plasma protein. β_2 -Glycoprotein-I is normally present at a concentration of 200 μ g/mL, is a member of the complement control protein family, and has five repeating domains and several alleles. An octapeptide in the fifth domain and critical cysteine bonds are necessary for both phospholipid binding and antigenicity;³ a first domain site is also implicated in pathogenicity. *In vivo*, β_2 GPI binds, primarily as a dimer or otherwise clustered, to phosphatidylserine on activated or apoptotic cell membranes, including those of trophoblasts, platelets and endothelial cells. This binding may initiate cell activation, clearance of apoptotic cells by macrophages,⁴ and/or coagulation.

Autoimmune aPL binds β_2 GPI (β_2 GPI-dependent aPL) or other phospholipid-binding proteins, which in turn binds negatively charged phospholipids. Drugs (such as chlorpromazine, procainamide, quinidine, and phenytoin), malignancies (such as lymphoproliferative disorders), and infectious agents (such as syphilitic and nonsyphilitic *Treponema*, *Borrelia Burgdorferi*, human immunodeficiency virus, *Leptospira*, or parasites) induce β_2 GPI-independent transient aPL (usually low-titer aCL, which may bind directly to the phospholipid) that are rarely associated with thrombosis.

EPIDEMIOLOGY

Low-titer aCL occurs in less than 10% of normal blood donors and moderate to high-titer aCL and/or a positive LA test occurs in less than 1%. The prevalence of positive aPL tests increases with age; because the

differential diagnosis of vascular occlusion is broader than it is in young adults, particular care is necessary in diagnosing APS in older patients. Thirty to 50% of SLE patients⁵ and approximately one-fifth of rheumatoid arthritis patients⁶ have positive tests for aPL.

The strength of association between aPL and clinical events varies between studies. A study of healthy male physicians followed prospectively for 3 years showed that those with moderate to high titers of IgG aCL have a risk for venous thrombosis or pulmonary embolus eight times higher than do men with negative tests.⁷ However, no risk-stratified, prospective, controlled studies of asymptomatic aPL-positive patients exist to determine an annual thrombosis rate in such patients, but estimates are 0–4%. Approximately 10% of first-stroke victims have aPL,⁸ especially those who are young,⁹ as do up to 21% of women who have suffered three or more consecutive fetal losses.¹⁰

ETIOPATHOGENESIS

Antiphospholipid antibodies exist as a family of autoantibodies directed against phospholipid-binding plasma proteins, most commonly β_2 GPI. The binding proteins of interest bind negatively charged phospholipids (cardiolipin, phosphatidylglycerol, phosphatidylserine, phosphatidylinositol), and not necessarily zwitterionic or neutral phospholipids (phosphatidylethanolamine, phosphatidylcholine). Other phospholipid-binding plasma proteins are prothrombin, thrombomodulin, high molecular weight kininogen, low molecular weight kininogen, antithrombin III, protein C, protein S, and annexins I and V.¹¹ *In vivo*, the likely relevant phospholipid to which these proteins bind is phosphatidylserine, normally on the inner cell membrane but exteriorized, and therefore made visible, during cell activation and apoptosis. Annexins bind to exposed phosphatidylserine and create a ‘remove me’ signal on cells.

The commonly accepted hypothesis regarding the origin of aPL states that an incidental exposure to environmental agents, the antigens of which contain β_2 GPI-like peptides, induces aPL in susceptible individuals via molecular mimicry.¹¹ In experimental animal models, passive or active immunization with viral peptides,¹² bacterial peptides,¹³ and heterologous β_2 GPI¹⁴ induce polyclonal aPL and clinical events associated with APS.

Table 61.1 Revised Sapporo Classification Criteria for the Antiphospholipid Syndrome.¹
Clinical criteria

1. Vascular thrombosis:¹

(a) One or more clinical episodes² of arterial, venous, or small vessel thrombosis³, in any tissue or organ

2. Pregnancy morbidity:

(a) One or more unexplained deaths of a morphologically normal fetus at or beyond the 10th week of gestation, or

(b) One or more premature births of a morphologically normal neonate before the 34th week of gestation because of eclampsia, severe pre-eclampsia, or recognized features of placental insufficiency⁴, or

(c) Three or more unexplained consecutive spontaneous abortions before the 10th week of gestation, with maternal anatomic or hormonal abnormalities and paternal and maternal chromosomal causes excluded

Laboratory criteria⁵

1. Lupus anticoagulant present in plasma, on two or more occasions at least 12 weeks apart, detected according to the guidelines of the International Society on Thrombosis and Hemostasis

2. Anticardiolipin antibody of IgG and/or IgM isotype in serum or plasma, present in medium or high titer (i.e. >40 GPL or MPL, or >the 99th percentile), on two or more occasions, at least 12 weeks apart, measured by a standardized enzyme-linked immunosorbent assay (ELISA).

3. Anti- β_2 glycoprotein-I antibody of IgG and/or IgM isotype in serum or plasma, (in titer >the 99th percentile) present on two or more occasions, at least 12 weeks apart, measured by a standardized ELISA

Definite APS is present if at least one of the clinical criteria and one of the laboratory criteria are met. Classification of APS should be avoided if less than 12 weeks or more than 5 years separate the positive aPL test and the clinical manifestation. In studies of populations of patients who have more than one type of pregnancy morbidity, investigators are strongly encouraged to stratify groups of subjects according to a, b, or c above.

¹Coexisting inherited or acquired factors for thrombosis are not reasons for excluding patients from APS trials. However, two subgroups of APS patients should be recognized, according to: (a) the presence, and (b) the absence of additional risk factors for thrombosis. Indicative (but not exhaustive) such cases include: age (>55 in men, and >65 in women), and the presence of any of the established risk factors for cardiovascular disease (hypertension, diabetes mellitus, elevated LDL or low HDL cholesterol, cigarette smoking, family history of premature cardiovascular disease, body mass index ≥ 30 kg/m², microalbuminuria, estimated GFR <60 mL/min), inherited thrombophilias, oral contraceptives, nephritic syndrome, malignancy, immobilization, and surgery. Thus, patients who fulfill criteria should be stratified according to contributing causes of thrombosis.

²A thrombotic episode in the past could be considered as a clinical criterion, provided that thrombosis is proved by appropriate diagnostic means and that no alternative diagnosis or cause of thrombosis is found.

³Superficial venous thrombosis is not included in the clinical criteria.

⁴Generally accepted features of placental insufficiency include: (i) abnormal or non-reassuring fetal surveillance test(s), e.g. a non-reactive non-stress test, suggestive of fetal hypoxemia, (ii) abnormal Doppler flow velocimetry waveform analysis suggestive of fetal hypoxemia, e.g. absent end-diastolic flow in the umbilical artery, (iii) oligohydramnios, e.g. an amniotic fluid index of 5 cm or less, or (iv) a postnatal birth weight less than the 10th percentile for the gestational age.

⁵Investigators are strongly advised to classify APS patients in studies into one of the following categories: I, more than one laboratory criteria present (any combination); IIa, LA present alone; IIb, aCL antibody present alone; IIc, anti- β_2 glycoprotein-I antibody present alone.

β_2 -glycoprotein-I polymorphisms influence the generation of aPL in individuals, but have only a weak relationship to the occurrence of aPL-related clinical events.¹⁵ Persons congenitally lacking β_2 GPI:¹⁶ and β_2 GPI-knockout mice¹⁷ appear normal.

In humans, although cross-sectional and prospective cohort studies demonstrate that aPL can predict future thrombosis, the pathogenic mechanism is unknown; more than one mechanism may be involved, as outlined in Table 61.2. Because high-titer antibody may persist for years in asymptomatic persons, and because positive aPL tests may precede symptoms for many years, it is likely that vascular injury and/or endothelial cell activation immediately precede thrombosis in those bearing the antibody. Platelet activation followed by binding of aPL to platelet membrane phospholipid-bound annexins may initiate platelet adhesion and thrombosis.¹⁸ Antiphospholipid antibodies may inhibit phospholipid-dependent reactions in the coagulation cascade, for example fibrinolysis, antithrombin III activity, or protein C and protein S activation.¹⁹ Interaction between aPL

KEY CONCEPTS

- >> Antiphospholipid antibodies (aPL) exist as a family of autoantibodies directed against phospholipid-binding plasma proteins, most commonly β_2 -glycoprotein-I.
- >> The origin of aPL is unknown but is hypothesized to be an incidental exposure to environmental agents inducing aPL in susceptible individuals.
- >> In humans, although cross-sectional and prospective cohort studies demonstrate that aPL can predict future thrombosis, the pathogenic mechanism is unknown; more than one mechanism may be involved.
- >> Concomitant prothrombotic risk factors may promote clotting in an additive manner in aPL-positive patients

Table 61.2 Possible mechanisms of aPL-induced thrombosis

Endothelial cells–aPL interaction
Endothelial cell damage or activation (via increased expression of adhesion molecules)
Coexisting anti-endothelial antibodies
aPL-induced monocyte adhesion to endothelial cells
Increased tissue factor expression
Platelet–aPL interaction
Platelet activation
Stimulation of thromboxane production
Coagulation system–aPL interaction
Inhibition of activation of protein C by the thrombomodulin–thrombin complex
Inhibition of activation of protein C via its cofactor protein S
Interaction between aPL and substrates of activated protein C such as Factors Va and VIIIa
Interaction between aPL and an annexin V anticoagulant shield
Complement activation

Table 61.3 The clinical spectrum of antiphospholipid antibodies (aPL)

Asymptomatic* aPL-positivity
Antiphospholipid syndrome with vascular events
Catastrophic antiphospholipid syndrome
Antiphospholipid syndrome with only pregnancy morbidity
Asymptomatic* aPL-positivity with noncriteria aPL manifestations

*No history of thrombosis or pregnancy morbidity as per the Sapporo Criteria [1]

thrombosis. In addition, aPL adversely affect the formation of a trophoblast syncytium, placental apoptosis, and trophoblast invasion, all processes required for normal establishment of placental function. *In vitro*, pathogenic aPL induce adhesion molecules and enhance adherence of leukocytes to cultured endothelial cells.

DIAGNOSIS

CLINICAL MANIFESTATIONS

The clinical manifestations of aPL represent a spectrum from asymptomatic to catastrophic APS (Table 61.3). The principal manifestations of APS are venous or arterial thromboses and pregnancy loss. Except for its severity, the youth of affected patients, and unusual anatomic locations (Budd–Chiari syndrome and sagittal sinus and upper extremity thromboses), thromboses in APS do not clinically differ from thromboses attributable to other causes. Stroke and transient ischemic attack are the most common presentation of arterial thrombosis, whereas deep vein thrombosis, often accompanied by pulmonary embolism, is the most common venous manifestation of APS. Glomerular capillary endothelial cell injury or thrombosis of renal vessels (thrombotic microangiopathy) causes proteinuria without celluria or hypocomplementemia and may lead to severe hypertension and/or renal failure.

Many patients have livedo reticularis (a lattice-like pattern of superficial skin veins) (Fig. 61.1), cardiac valve disease (vegetations, valve thickening and dysfunction), or other nonthrombotic manifestations described in several studies but not included in the revised Sapporo criteria¹ owing to nonspecificity or rarity (Table 61.4). These manifestations do not by themselves classify a patient as having APS for clinical studies, but they add information to the diagnosis of individual patients. The pathogenesis of cardiac valve disease in APS is unknown; valve replacement may be necessary. A putative association of aPL and increased risk of atherosclerosis exists but is controversial; in studies of atherosclerosis in patients with SLE, aPL protected against atherosclerosis.²⁴ Some patients develop nonfocal neurologic symptoms, such as lack of concentration, forgetfulness, and dizzy spells. Multiple small, hyperintense lesions seen on magnetic resonance imaging (MRI), primarily in the periventricular white matter, do not correlate well with clinical symptoms (Fig. 61.2).

Pregnancy losses in patients with aPL typically occur after 10 weeks’ gestation (fetal loss), but early losses also occur (pre-embryonic or embryonic losses).²⁵ APS patients may develop severe, early pre-eclampsia and HELLP

and an annexin V anticoagulant shield is another proposed but less well accepted mechanism.²⁰ Recent studies also demonstrate that aPL increase tissue factor (a physiologic initiator of coagulation) expression on monocytes.²¹ A cluster of 50 upregulated genes may distinguish between aPL-positive patients with and without thrombosis.²²

In experimental animal models, aPL causes fetal resorption (a proxy for recurrent fetal loss) and increase in size and duration of trauma-induced venous and arterial thrombi. Inhibiting complement activation prevents experimental aPL-induced fetal death, and C5 knockout mice carry pregnancies normally despite the presence of aPL, implying that a complement-mediated effector mechanism is an absolute requirement for fetal death to occur.²³

In the currently accepted ‘second-hit hypothesis,’ a second trigger event (such as oral contraceptive use or surgical procedures), which may not otherwise be sufficient to cause thrombosis, may be necessary for an asymptomatic aPL-positive patient to develop thrombosis. Acquired (oral contraceptive use) and heritable thrombotic risk factors (deficiencies of protein C, protein S, or antithrombin III; mutations of factor V [A506G, factor V_{Leiden}], prothrombin [G20210A], or methylene tetrahydrofolate reductase [MTHFR C677T, hyperhomocysteinemia]) may increase the risk of aPL patients (see Table 61.1 footnote).

A proposed pathogenesis for aPL-mediated thrombosis and placental injury begins with the activation or apoptosis (by unknown triggers, possibly infectious or traumatic) of platelets, endothelial cells, or trophoblast. The negatively charged phosphatidylserine migrates from the inner to the normally electrically neutral outer cell membrane. Circulating β₂GPI then binds to phosphatidylserine, followed by the aPL binding to a β₂GPI dimer, activating complement and, through C5a, initiating a signaling cascade that induces cell surface tissue factor (TF) expression and adhesion molecules (e.g., ICAM-1). Other components of the innate immune system can also be activated. Platelets aggregate and initiate

Fig. 61.1 Livedo reticularis in a patient with primary antiphospholipid syndrome.

(hemolysis, elevated liver enzymes, low platelets) syndrome. Although placental infarction may be a cause of fetal growth restriction or death, nonthrombotic mechanisms of placental dysfunction are probably more important.

Catastrophic APS (CAPS) is a rare, abrupt, life-threatening complication. It consists of multiple thromboses of medium and small arteries occurring (despite apparently adequate anticoagulation) over a period of days, causing stroke, cardiac, hepatic, adrenal, renal, and intestinal infarction and peripheral gangrene. Proposed formal criteria for this syndrome are shown in Table 61.5.²⁶ Acute adrenal failure may be the initial clinical event, often heralded by unexplained back pain and vascular collapse (e.g., severe hypotension). CAPS patients often have moderate thrombocytopenia; erythrocytes are less fragmented than in the hemolytic-uremic syndrome or thrombotic thrombocytopenic purpura; fibrin split products are not strikingly elevated. Renal failure and pulmonary hemorrhage may occur. Tissue biopsies show noninflammatory vascular occlusion of both very small and medium-sized vessels.

Antibodies to prothrombin (factor II) sometimes accompany aPL²⁷ and may cause hemorrhage by depleting prothrombin (lupus anticoagulant hypoprothrombinemia syndrome).²⁸

LABORATORY TESTS

In the presence of characteristic clinical events, APS is diagnosed when patients have persistent aPL that includes moderate- to high-titer IgG and/or IgM aCL, moderate- to high-titer IgG and/or IgM $\alpha\beta_2$ GPI, and/or positive lupus anticoagulant test.¹ Approximately 80% of patients with positive LA tests have aCL, and 20% of patients positive for aCL

Fig. 61.2 Magnetic resonance imaging demonstrating multiple periventricular white matter hyperintense lesions.

have positive LA tests. IgA aCL can occur rarely as the only aPL in APS patients; some of these patients are aCL negative, but only $\alpha\beta_2$ GPI positive. These tests (IgA aCL and $\alpha\beta_2$ GPI), when positive, justify a diagnosis of APS in LA and aCL IgG/M test-negative patients with clinically typical disease. Lupus anticoagulant test-positive patients have a higher risk for thrombosis than do LA test-negative patients.¹ Although several studies state that $\alpha\beta_2$ GPI-positive patients are also at higher thrombosis risk, these claims are inconsistent.²⁹

The lupus anticoagulant test is a functional coagulation assay that measures the ability of aPL to inhibit the conversion of prothrombin to thrombin. Guidelines of the International Society on Thrombosis and Hemostasis³⁰ for the diagnosis of LA require: (a) demonstration of a prolonged phospholipid-dependent coagulation screening test, such as activated partial thromboplastin time (aPTT) or dilute Russell viper venom time (dRVVT); (b) failure to correct the prolonged screening test by mixing the patient plasma with normal platelet-poor plasma, demonstrating the presence of an inhibitor; (c) shortening or correction of the prolonged screening test by the addition of excess phospholipid, demonstrating phospholipid dependency; and (d) the exclusion of other coagulopathies. A positive screening coagulation test without confirmatory steps is not a positive LA test.

Interpretation of positive tests should take into account the following rules: moderate- to high-titer (> 40 U) aCL is more strongly associated with clinical events than is low-titer aCL;¹ LA is a more specific but less

Table 61.4 Noncriteria features of the antiphospholipid syndrome

Type	Features
Clinical	Livedo reticularis Cardiac valve disease Autoimmune hemolytic anemia Thrombocytopenia (usually 50 000–100 000/mm ³) Multiple sclerosis-like syndrome and other myelopathy Nonfocal neurologic symptoms Chorea
Laboratory	IgA anticardiolipin and anti- β_2 -glycoprotein-I antibodies Anti-phosphatidylserine, phosphatidylinositol, phosphatidylglycerol, phosphatidylethanolamine antibodies Anti-prothrombin antibodies Anti-phosphatidylserine–prothrombin antibodies

Table 61.5 Preliminary criteria for the classification of catastrophic APS²⁶

1. Evidence of involvement of three or more organs, systems, and/or tissues ¹
2. Development of manifestations simultaneously or in less than 1 week
3. Confirmation by histopathology of small vessel occlusion in at least one organ or tissue ²
4. Laboratory confirmation of the presence of aPL ³
Definite catastrophic APS: All four criteria
Probable catastrophic APS: Criteria 2–4 and two organs, systems and/or tissues involved Criteria 1–3, except no aPL confirmation 6 weeks apart due to the early death of a patient not tested before catastrophic episode Criteria 1, 2, 4; or Criteria 1, 3, 4 and development of a third event more than 1 week but less than 1 month after first, despite anticoagulation
¹ Usually, clinical evidence of vessel occlusions, confirmed by imaging techniques when appropriate. Renal involvement is defined by a 50% rise in serum creatinine, severe systemic hypertension and/or proteinuria. ² For histopathological confirmation, significant evidence of thrombosis must be present, although vasculitis may occasionally coexist. ³ If the patient had not been previously diagnosed as having APS, laboratory confirmation requires that presence of aPL must be detected on two or more occasions at least 6 weeks apart (not necessarily at the time of the event), according to the proposed preliminary criteria for the classification of APS.

sensitive predictor of thromboses than is aCL³¹; multiple positive aPL tests impart a worse prognosis than does any single type of test; and positive aPL tests require a repeat test after 12 weeks to exclude transient aPL.¹

Laboratory variability in these assays is moderately high: stability of assay in individual patients over time is assured about 80% of the time.³² Based on same-day specimens, the consistency of aCL results among different commercial laboratories ranges from 64% to 88%, with moderate agreement for IgG and IgM, and with marginal agreement for aCL IgA.³²

Antiphospholipid antibody tests developed based on phosphatidylserine, phosphatidylinositol, phosphatidylethanolamine or prothrombin are not well standardized or widely accepted; their clinical significance is unknown. A false positive test for syphilis is not diagnostic for APS.

Antinuclear and anti-DNA antibodies occur in approximately 45% of APS patients who are not diagnosed as having SLE. Thrombocytopenia in APS is usually modest (>50 000/mm³); proteinuria and renal insufficiency occur in patients with thrombotic microangiopathy. Erythrocyte sedimentation rate (ESR), hemoglobin, and leukocyte count are usually normal in patients with uncomplicated APS, except during acute thrombosis. Complement levels are usually normal or only modestly low.

IMAGING STUDIES

Magnetic resonance imaging (MRI) studies show vascular occlusion and infarction consistent with clinical symptoms, without special characteristics, except that multiple otherwise unexplained cerebral infarctions in a

CLINICAL PEARLS

- >> The clinical manifestations of aPL represent a spectrum (from asymptomatic to catastrophic antiphospholipid syndrome [APS]); thus patients should not be evaluated and managed as having a single disease manifestation.
- >> Stroke and transient ischemic attack are the most common presentation of arterial thrombosis; deep vein thrombosis, often accompanied by pulmonary embolism, is the most common venous manifestation of APS.
- >> Pregnancy losses in patients with aPL typically occur after 10 weeks' gestation (fetal loss), but early losses also occur (pre-embryonic or embryonic losses).
- >> Catastrophic APS is a rare, abrupt, life-threatening complication of APS, which consists of multiple thromboses of medium and small arteries occurring over a period of days.
- >> Antiphospholipid syndrome diagnosis should be made in the presence of characteristic clinical manifestations and *persistently* (at least 12 weeks apart) positive aPL.

young person suggest the syndrome. Multiple small hyperintense white matter lesions are common and do not unequivocally imply brain infarction (Fig. 61.2). Occlusions usually occur in vessels below the resolution limits of angiography; hence angiography or magnetic resonance angiography is not indicated unless clinical findings suggest medium or large vessel disease. Echocardiography or cardiac MRI may show severe Libman-Sacks endocarditis and intracardiac thrombi.

PATHOLOGIC STUDIES

Skin, renal, and other tissues show noninflammatory occlusion of all caliber arteries and veins, acute and chronic endothelial injury and its sequelae, and recanalization in late lesions. The finding of inflammatory necrotizing vasculitis suggests concomitant SLE or other connective tissue disease. There are no other diagnostic immunofluorescence or electron microscopic findings.

TREATMENT

Treatment recommendations for persistently aPL-positive patients are summarized in Table 61.6. Anticoagulation with unfractionated heparin or low molecular weight heparin (LMWH) followed by warfarin is the treatment for APS patients with vascular events. Heparin inhibits complement, a fact that theoretically makes it a preferred but impractical agent except in the treatment of pregnancies. For those patients with a positive LA test that elevates the aPTT, the heparin dose can be monitored by measuring peak and trough activated Factor Xa levels. For well-anticoagulated patients who continue to have thromboses, antiplatelet drugs, hydroxychloroquine, statins, intravenous immunoglobulin (IVIG), and plasmapheresis have a theoretical basis for efficacy and have all been used. Rituximab is under experimental evaluation. Clinical experience suggests that thrombolytic agents for acute thrombosis are unhelpful,

because re-occlusion rapidly occurs. There are no systematic studies of treatment for catastrophic APS. Detailed reviews conclude that the most effective treatment combines full-dose anticoagulation, high-dose corticosteroid, plasma exchange, and IVIG.³³

Recent prospective controlled studies conclude that recurrence of thromboses in APS patients can be prevented with moderate-intensity warfarin to an international normalized ratio (INR) of 2.0–3.0.^{34, 35} Although these studies provide strong evidence for moderate-intensity anticoagulation following an aPL-related venous event, the intensity of the anticoagulation is still a matter of debate for APS patients with arterial events, because such patients constituted a minority of patients in these controlled studies. Although some APS patients may require high-intensity anticoagulation, in the absence of risk-stratified studies the definition of high-risk is currently based on clinical judgment. No prospective controlled data demonstrate the superiority of high-intensity anticoagulation in APS patients.

Most aPL-positive patients receive warfarin after ischemic strokes; however, the Antiphospholipid Antibody in Stroke Study (APASS) concluded that for selected aPL-positive patients who have neither atrial fibrillation nor high-grade arterial stenosis, aspirin and warfarin therapy (at an INR of 2.2) are equivalent in both efficacy and major bleeding complications.³⁶ The generalizability of these results is limited, however, as the study group had an average age of 60 years (much higher than the average for APS population), the aPL determination was performed only once at study entry, and the cut-off for assigning a patient to the positive aCL group was very low. However, based on APASS results, aspirin is an option for patients with a single low positive aCL test who present with stroke.

Venous thrombosis in aPL-positive patients has a high recurrence rate if anticoagulation is discontinued, and lifelong anticoagulation is usually recommended. It is unknown whether patients whose event was triggered by an acquired and reversible thrombotic risk factor can discontinue anticoagulation or switch to aspirin when the trigger factor is eliminated. Normalization of the LA or aCL tests is *not* a clear indication to discontinue anticoagulation.

Asymptomatic persons serendipitously found to have aPL need no preventive therapy. Elimination of reversible thrombosis risk factors (smoking, oral contraceptives) and prophylaxis during high-risk periods (such as surgical interventions or prolonged immobilization) are advised for primary thrombosis prophylaxis in persistently aPL-positive individuals. The necessity for and effectiveness of low-dose aspirin in asymptomatic aPL-positive patients remains to be demonstrated. Estrogen and estrogen-containing oral contraceptives are deemed unsafe for APS patients, or even for asymptomatic women serendipitously known to bear high-titer antibody. There is no reliable information regarding the safety of progestin-only contraceptives, 'morning after' contraception, or raloxifene, bromocriptine, or leuprolide in APS patients. However, progestin-only contraception is theoretically safer than estrogen-based contraception. A small retrospective review of women undergoing artificial reproductive technology (IVF) procedures demonstrated no thrombotic events.

Persistence of aPL for decades without clinical events is well documented, although some patients with positive aPL tests have clinical events of ambiguous meaning (dizzy or confusional episodes, nonspecific visual disturbance, very early pregnancy loss). There is no consensus for the treatment of such persons. Because full anticoagulation carries a high risk, many physicians prescribe low-dose (81 mg) aspirin daily and/or hydroxychloroquine. No published data support or repudiate this

Table 61.6 Treatment recommendations in persistently antiphospholipid antibody-positive patients

Clinical circumstance	Recommendation
Asymptomatic	No treatment*
Venous or arterial thrombosis	Warfarin INR 2–3.0 indefinitely
Recurrent thrombosis	Warfarin INR 3–3.5 indefinitely ± low-dose aspirin
First pregnancy	No treatment*
Single pregnancy loss, < 10 weeks	No treatment*
Recurrent fetal loss or loss after 10 weeks, history of no thrombosis	Prophylactic dose** heparin with low-dose aspirin throughout the pregnancy, discontinue heparin 6–12 weeks postpartum
Recurrent fetal loss or loss after 10 weeks, history of thrombosis	Therapeutic dose heparin*** with low-dose aspirin throughout pregnancy, warfarin postpartum
Catastrophic APS	Anticoagulation + corticosteroids + intravenous immunoglobulin or plasma exchange
Livedo reticularis	No treatment
Valve nodules or deformity	No known effective treatment; full anticoagulation if emboli or intracardiac thrombi is demonstrated
Thrombocytopenia > 50 000/mm ³	No treatment
Thrombocytopenia, < 50 000/mm ³	Prednisone and/or intravenous immunoglobulin

*Aspirin 81 mg/day may be given
 **Prophylactic dose such as enoxaparin 30–40 mg subcutaneously (SQ) once daily.
 ***Therapeutic dose such as enoxaparin 1 mg/kg SQ twice daily or 1.5 mg/kg SQ once daily

recommendation. Corticosteroids and/or IVIG are the first-line treatments for platelet counts less than 50 000/mm³.

Pregnancy is a prothrombotic state; management strategies in persistently aPL-positive patients should focus on prevention of both pregnancy morbidity and maternal thrombotic complications.³⁷ In pregnancy, a combination of heparin and low-dose aspirin increases fetal survival rate from 50% to 80% among women who have had a fetal loss and who have unequivocally positive tests for aPL. If patients fail this regimen, the next step is to add IVIG, an approach not supported by controlled studies. Most experts in the field now use LMWH such as enoxaparin because of the lower risk of thrombocytopenia and osteoporosis: prophylactic doses for women who have had only pregnancy morbidity, or full anticoagulant doses for women who have had prior thromboses (Table 61.5). Treatment begins after confirmation of pregnancy, continues until 48 hours before anticipated delivery (to allow epidural anesthesia), and resumes for 8–12 weeks postpartum. No studies unequivocally justify the treatment of young women with aPL during a first pregnancy, women with only very early losses, or women whose aPL titers are low or transient. Nonetheless, it is common to offer such patients low-dose aspirin.

Serious perioperative complications may occur despite prophylaxis. APS patients are at additional risk for thrombosis when they undergo surgery. Thus, perioperative strategies should be clearly identified before any surgical procedure, pharmacological and physical anti-thrombosis interventions vigorously employed, periods without anticoagulation kept to an absolute minimum, and any deviation from a normal course be considered a potential disease-related event.³⁸

THERAPEUTIC PRINCIPLES

- >> Secondary thrombosis prevention in persistently aPL-positive individuals lack a risk-stratified approach; although the current recommendation is lifelong warfarin, the *intensity* and *duration* of warfarin treatment are still debated. The effectiveness of high-intensity anticoagulation in APS patients with vascular events is not supported by prospective controlled studies.
- >> Primary thrombosis prevention in persistently aPL-positive individuals lacks an evidence-based approach; elimination of reversible thrombosis risk factors and prophylaxis during high-risk periods (such as surgical procedures) are crucial.
- >> Catastrophic APS patients usually receive a combination of anticoagulation, corticosteroids, intravenous immunoglobulin (IVIG), and plasma exchange.
- >> A common strategy to prevent fetal loss in aPL-positive patients with history of pregnancy morbidities is low-dose aspirin and heparin; if patients fail this regimen, the next step is to add IVIG, although this approach is not supported by controlled studies.
- >> Currently, there is no evidence that anticoagulation is effective for nonthrombotic manifestations of aPL, such as livedo reticularis, thrombocytopenia, hemolytic anemia, or heart valve disease.

Experimental (for statins) and retrospective and cross-sectional clinical studies (for statins and hydroxychloroquine) suggest that these agents improve overall prognosis in APS patients.³⁹ Prospective controlled studies to determine primary and secondary thrombosis prevention in APS are not available. Antiplatelet agents other than aspirin, long-term LMWH treatment, or direct/indirect thrombin inhibitors, empirically used, have not been formally tested in clinical trials. Platelet glycoprotein IIb/IIIa-specific antagonists, P38MAPK inhibitors, thromboxane A2 inhibitors, tissue factor expression inhibitors, complement inhibitors, and synthetic peptides, may be candidates for future clinical trials.³⁹

CONCLUSION

Antiphospholipid syndrome is a systemic autoimmune systemic disease consisting of thromboses, pregnancy losses, and persistent high-titer aPL. Concomitant prothrombotic risk factors may increase the risk for clotting. The differential diagnosis is broad, especially in older patients: the use of strict diagnostic criteria can help prevent over-diagnosis.

Complement activation and inflammation are established mechanisms of aPL-related murine pregnancy loss but not yet confirmed in human pregnancy loss or in aPL-associated nongravid thrombosis. Anticoagulation is the primary treatment today, but a future therapeutic approach will probably include immunomodulatory agents with or without antithrombotics.

IMMUNE-MEDIATED ANEMIA

Immune-mediated hemolysis can be autoimmune or alloimmune, idiopathic or secondary to drugs or other diseases, but it consistently involves either immunoglobulin G (IgG) or IgM (rarely IgA) antibodies to antigens on the red cell membrane (Table 62.1).^{1,2}

ANTI-ERYTHROCYTE ANTIBODIES AND THEIR ANTIGENS

The antigens for anti-erythrocyte IgG are usually proteins, including the clinically important antigens (D, C, c, E, e) on the Rh-associated glycoprotein (RhAG).³ In contrast, anti-erythrocyte IgM is directed at polysaccharides, which include the ABO and I-antigens (I, i) found on the anion and glucose transporter proteins in the red cell membrane.^{4,5} During the first few months after birth isoantibodies to A and B develop if these antigens are absent on the neonate's red cells. The isoantibodies presumably follow exposure to A and B antigens present on plants and bacteria ubiquitous in the environment.

IgG and IgM antibodies are also distinguished by being 'warm-' and 'cold-' reactive respectively, meaning that they can bind to their antigens at core body temperature (warm) or they bind preferentially at lower temperatures (cold) in the peripheral circulation or *ex vivo*. This distinction results from the different thermodynamics of binding to protein (hydrophobic) and polysaccharide (electrostatic) antigens.⁵

IgG and IgM also differ in their ability to fix complement, and this affects their mechanism of hemolysis. In order to attach the first component of complement, two IgG molecules must bind to the red cell in close proximity. However, because of its pentameric structure, a single IgM molecule can initiate complement activation.

MECHANISMS OF ANTIBODY-MEDIATED HEMOLYSIS

Erythrocyte-bound IgG becomes attached to the Fc receptors of splenic macrophages, which may engulf all or part of the cell or release lysosomal enzymes that digest its membrane (antibody-dependent

cell-mediated cytotoxicity: ADCC).⁶ Red cell fragments escaping from this encounter lose more membrane than cytoplasm and become spherical to compensate for this change in their surface-to-volume ratio. If IgG has initiated complement activation on the cell surface, phagocytosis in the spleen will be augmented by binding of C3b to splenic macrophages.⁷

When IgM fixes complement, the process begins in the cooler peripheral circulation where the IgM can bind to the red cells. If the amount of IgM bound is relatively high and if at least some of it remains on the cell at 37°C (e.g., anti-A or anti-B isoantibodies), the cascade of complement reactions goes to completion. Doughnut-shaped holes are formed in the cell membrane that allow the influx of water and sodium, inducing intravascular osmotic rupture of the cell.⁶ However, if the IgM elutes from the red cell as it returns to body core temperature, the complement reactions diminish. Under these circumstances the components remain on the cell but do not cause intravascular hemolysis. Instead, they can be cleared by hepatic macrophages with complement-binding sites.⁸

PATHOPHYSIOLOGIC CONSEQUENCES OF HEMOLYSIS

Antibody-mediated hemolysis causes variable degrees of anemia and reticulocytosis. Intravascular hemolysis releases hemoglobin into the circulation. However, the amount of hemoglobin swept away as macrophages are engulfing red cells is generally too small to cause measurable hemoglobinemia, but it will result in consumption of haptoglobin, which quickly becomes depleted. In contrast, when hemolysis results from by complement-mediated lysis, such as follows an ABO-incompatible blood transfusion, hemoglobinemia becomes massive, overcoming the scavenging capacity of plasma hemoglobin binders (haptoglobin, hemopexin, albumin) and resulting in hemoglobinuria. Because hemoglobin is toxic to the renal tubular epithelium, renal function may become impaired. Red cell membrane fragments released by massive intravascular hemolysis are procoagulant and can cause disseminated intravascular coagulation.

The consequences of extravascular hemolysis (i.e., by phagocytosis) are much less severe. In macrophages iron is removed from the hemoglobin

Table 62.1 Classification of immune hemolytic disorders**Autoimmune****Warm antibody-mediated****Idiopathic****Secondary**

Drugs, lymphoid malignancies, infections

Other autoimmune diseases

Cold antibody-mediated**Cold agglutinin disease****Idiopathic****Secondary**

Infection, lymphoid malignancies

Paroxysmal cold hemoglobinuria**Idiopathic****Secondary to infections****Alloimmune**

Secondary to red cell transfusions (alloantibodies, isoantibodies)

Secondary to fetomaternal hemorrhage

Secondary to transplanted lymphocytes

and recycled to the circulation to support a compensatory reticulocytosis while the heme porphyrin is metabolized to bilirubin.

TESTING FOR RED CELL ANTIBODIES

With few exceptions, if the mechanism is immune-mediated, an anti-red cell antibody can be demonstrated, either on the red cell surface, in the serum or in both circumstances.^{1,2} With autoimmune hemolysis immunoglobulin (IgG or IgM) and/or complement components can be identified by a direct antibody test (DAT), originally known as a direct Coombs test (Fig. 62.1). For this assay a patient's red cells are washed and suspended in buffer. Surface-bound IgG is detected by adding anti-IgG antibody, which, being divalent, can bind to IgG on adjacent red cells and agglutinate them into visible aggregates. Because of its pentameric structure, IgM on the cells can cause agglutination without the addition of a second antibody. Even when IgM has previously eluted from the cell surface, its earlier presence *in vivo* can be detected by telltale remnants of complement that are fixed to the red cell. Detection requires the addition of anti-complement (e.g., anti-C3dg) antibody.

Alloantibodies can also be detected by the DAT if allogenic red cells are still circulating from a previous transfusion. If these have been cleared, however, red cell antibodies can be identified in the patient's serum by adding the serum to a panel of red cells carrying different antigens. Agglutination is detected as described above; this constitutes the indirect antibody test.

AUTOIMMUNE HEMOLYSIS MEDIATED BY WARM ANTIBODY

Although warm-antibody autoimmune hemolytic anemia is rare, it increases in prevalence above the age of 50 and tends to be more common in women than in men. In this condition the DAT is positive

for IgG and may also be positive for complement components. Although the autoantibody is most often against an Rh antigen, a variety of other antigens have also been targeted. The specificity of the antibody, however, does not affect the presentation or management of the disease.

The short-term prognosis of warm-antibody hemolysis depends upon the severity of the anemia, which can develop rapidly and be fatal if not properly treated.¹ The long-term prognosis depends upon the underlying disease when present (Table 62.1) and upon the risks of chronic immunosuppression, which is often required to control the disease. Based upon series of patients treated 40–50 years ago, the overall mortality related to warm-antibody autoimmune hemolysis in adults is 20–40% over 10 years.² More recent estimates are not available, but surely must be less. In children the prognosis is better because many cases are related to infections and therefore transient.⁹ The estimated mortality is 11%, all due to chronic cases indistinguishable from that in adults.

If the anemia is severe, the patient must be transfused with allogenic red cells, which will be destroyed as rapidly as the patient's own red cells but may be life-saving nevertheless. The challenge for the transfusion service is to avoid giving the patient blood that could cause an additional acute hemolytic reaction due to alloantibodies from previous transfusions or pregnancy. Alloantibodies can be detected using the patient's own cells that have been stripped of autoantibody.¹⁰ Since these are autologous, they can be used to adsorb more autoantibody from the patient's serum, while leaving behind any alloantibodies, which can be detected once the autoantibody has been completely removed.

The mainstay of treatment is immunosuppression with corticosteroids, which usually produce significant benefit within 2 weeks.^{1,11} About 20% of patients achieve a lasting remission with steroids and can stop therapy. The majority, however, require continuous treatment. When long-term steroid treatment is too toxic, splenectomy is usually the next treatment, preferably done laparoscopically. This often produces complete responses. If splenectomy fails, however, a variety of other immunosuppressant medications can be tried (e.g., azathioprine, danazol, rituximab, cyclosporine).

DRUG-INDUCED IMMUNE HEMOLYSIS

Over 100 drugs have been associated with immune hemolysis.¹² Second- and third-generation cephalosporins currently account for over 80% of cases. The prognosis of this type of immune hemolysis is much better than that of the idiopathic variety because the hemolysis stops once the offending drug has been removed.

Although the biochemical mechanisms leading to drug-related immune hemolysis are not completely clear, several hypotheses are generally accepted. The most common cases appear to be mediated by immune complexes of drug and IgG and/or IgM that adsorb to the red cell surface where they fix complement. The resultant hemolysis is acute and often severe enough to cause renal failure.

A second mechanism is far less common and develops primarily in patients receiving very high doses of penicillin (rarely used any more) for at least a week. High-titer anti-penicillin IgG develops and binds to penicillin that is covalently attached to the red cell membranes. The resultant hemolysis is less acute than that caused by immune complexes but can be life-threatening.

In a third mechanism the drug stimulates the production of an antibody that reacts with the patient's red cells independently of the drug. Serologically this antibody is indistinguishable from an idiopathic autoantibody. These autoantibodies have become rare as the use of the primary

Fig. 62.1 The direct antibody test (DAT). The test is positive when immunoglobulin G (IgG; light blue triangles)-coated red cells are cross-linked by anti-IgG antibody (dark blue triangles) to form visible cell aggregates. Cell-bound complement and/or IgM can be detected by using anti-complement or anti-IgM reagent antibodies.

causal agent, methyldopa, has dwindled. Although these autoantibodies commonly cause positive DATs, they rarely actually cause hemolysis, and when they do, it usually ceases within 2 weeks of discontinuing the drug.

HEMOLYTIC DISEASE OF THE NEWBORN (HDN)

When a fetus inherits red cell antigens unshared by its mother and when the mother becomes immunized against these antigens by fetal–maternal hemorrhage during delivery, there is the possibility that subsequent fetuses will suffer intrauterine and postnatal hemolysis caused by maternal alloantibodies.¹³ The majority of anti-A and anti-B isoantibodies are not a problem because they are IgM, and cannot traverse the fetoplacental circulation. Although a variety of antigenic incompatibilities can cause HDN, Rh (specifically D antigen) is the most common. The incidence of HDN has dropped dramatically since 1968 when routine prophylaxis for Rh-negative new mothers began. Since then, mothers at risk receive

intramuscular anti-D after delivery to destroy any fetal cells in their circulation before they can induce a maternal immune response.

The severity of HDN varies from mild jaundice to life-threatening anemia and brain-damaging hyperbilirubinemia (kernicterus) to intrauterine death (fetal hydrops). Treatment varies from irradiation of jaundiced infants with fluorescent lights to postpartum exchange transfusion or intrauterine transfusion.

HEMOLYTIC TRANSFUSION REACTIONS

Because individuals with group O red cells have preformed isoanti-A and -B, they must only be transfused with group O cells. Similarly, individuals with group A red cells and therefore anti-B isoantibodies must only receive group A red cells, and individuals with group B red cells must only receive group B red cells. Because of the absence of either group A or B antigens on the surface of group O red cells, such cells can be used in transfusion of A, B, or AB individuals in emergent situations. Failure to abide by these rules results in acute intravascular hemolysis that can cause renal failure, disseminated intravascular coagulation, and death.

Other hemolytic transfusion reactions are caused by alloantibodies, predominantly IgG. Therefore, a multiply-transfused patient is at risk for hemolysis from alloantibodies if the patient receives incompatible blood. Multiparous women are at similar risk because of exposure to foreign fetal red cell antigens. Fortunately, for unclear reasons, most red cell antigens do not elicit an immune response. The most immunogenic are the Rh, Kell, Kidd, and Duffy. However, exposure particularly to Kidd or Duffy antigens may stimulate alloantibody formation that can rise to sufficient titer to cause hemolysis a week later. Such delayed transfusion reactions may be subtle or cause an abrupt drop in hemoglobin with jaundice and hemoglobinuria.

IMMUNE HEMOLYSIS ASSOCIATED WITH TRANSPLANTATION

Any transplanted tissue may contain ‘passenger’ lymphocytes that will survive if the recipient is sufficiently immunosuppressed.¹⁴ When the red cells of the recipient carry A- or B-antigen and the donor is ABO-incompatible, the transplanted lymphocytes will respond to the recipient red cells as foreign, and alloanti-A or anti-B antibodies will be produced that can lead to significant hemolysis. If the transplant involves hematopoietic stem cells, this dilemma will resolve once the donor’s erythropoiesis prevails and the donor lymphocytes are no longer exposed to recipient red cells.

COLD AGGLUTININ DISEASES

These are mediated predominantly by anti-I or anti-i IgM that agglutinates red cells at temperatures below 37°C.¹⁵ Red cell aggregates formed in the cooler peripheral circulation can obstruct small vessels and lead to acrocyanosis. In addition, complement fixed to red cells induces clearance, primarily by liver macrophages, causing varying degrees of anemia. The severity of the clinical illness depends upon the concentration of the IgM and its “thermal amplitude.” Thermal amplitude describes the temperature dependence of its binding to red cells: for example, antibodies that exclusively bind at 4°C are only active *in vitro*, whereas those that bind at >30°C can bind to red cells in the peripheral circulation and begin the process of complement fixation, which can be continued as the cells return to body core

THERAPEUTIC PRINCIPLES

Hemolytic anemia induced by 'warm' antibody

Acute: corticosteroids, transfusion if severe

Chronic: splenectomy, immunosuppression

Hemolytic anemia induced by 'cold' antibody

Cold agglutinin disease: avoidance of cold; alkylating agents; fludarabine

Paroxysmal cold hemoglobinuria: avoidance of cold; corticosteroids

Hemolytic disease of the newborn

Neonatal exposure to fluorescent light

Intrauterine transfusion or exchange transfusion

temperatures. The activity of the IgM is also determined by its relative affinity for the I- and i-antigens, which vary from one individual to the next.

Two general types of cold agglutinin disease are recognized: a chronic idiopathic disease presenting in patients over age 50 and caused by monoclonal IgM, and a transient disease secondary to certain infections (e.g., mycoplasma, Epstein-Barr virus, cytomegalovirus) and caused by polyclonal IgM (Table 62.1). Both categories of cold agglutinin disease can often be managed simply by avoiding cold environments. The chronic disease, however, may require alkylating agents (e.g., cyclophosphamide) or fludarabine while corticosteroids and splenectomy are not effective.

PAROXYSMAL COLD HEMOGLOBINURIA

Paroxysmal cold hemoglobinuria (PCH) is caused by anti-P IgG that is very effective in fixing complement and producing intravascular hemolysis.² Although rare, it is most common in children following a viral illness and can be managed by avoidance of cold. In the past it was more commonly associated with syphilis (Table 62.1). There is also an autoimmune variety of PCH that may require immuno-suppression with corticosteroids. Because the hemolysis is intravascular, however, splenectomy is not helpful.

IMMUNE NEUTROPENIA

CLASSIFICATION

The term immune neutropenia describes a heterogeneous group of acquired diseases in which the immune system selectively reduces circulating neutrophils to below 1500 cells/mm³ (Table 62.2).

ISOIMMUNE NEONATAL NEUTROPENIA¹⁶

Transient neutropenia analogous to neonatal immune hemolysis or thrombocytopenia develops when IgG anti-neutrophil antibodies from an allo-sensitized or autoimmune mother cross the placenta and destroy fetal neutrophils. Neutropenia is typically present at birth, and resolves spontaneously as maternal antibodies usually disappear within 12–15 weeks but sometimes may persist as long as 24 weeks postpartum.

Table 62.2 Causes of immune neutropenia

Primary

Isoimmune neonatal neutropenia

Autoimmune neutropenia of childhood

Adult autoimmune neutropenia

Secondary**Systemic autoimmune disease**

Rheumatoid arthritis, i.e., Felty's syndrome

Systemic lupus erythematosus

Sjögren's syndrome

Lymphoproliferative malignancy

Large granular lymphocyte (LGL) leukemia

Lymphoma

Drug-induced

Anti-thyroid medications – propylthiouracil, methimazole

Antibiotics – penicillin, cephalosporins

Many other drugs associated with agranulocytosis,

but definitive proof of an immune origin is often absent

PRIMARY AUTOIMMUNE NEUTROPENIA¹⁷

Primary autoimmune neutropenia is an antibody-mediated disease that is most common in early childhood. Patients typically have normal blood counts at birth, and develop neutropenia at 3–36 months of age. Children presenting at less than 2 years of age most commonly recover spontaneously within 2–3 years of diagnosis. Nevertheless, some children, particularly those presenting at older ages or manifesting other autoimmune findings, develop a chronic neutropenia disorder. Primary immune neutropenia (in the absence of other disease manifestations) is less common in adults. Rigorous incidence data are unavailable, but a small retrospective study in Sheboygan county, Wisconsin, found an annual incidence of 5–10 cases of primary or secondary neutropenia per 100 000 people.

FELTY'S SYNDROME¹⁸

Immune neutropenia develops in about 1% of patients with rheumatoid arthritis, most commonly (but not exclusively) in association with splenomegaly, a pattern designated Felty syndrome. Patients typically express human leukocyte antigen (HLA)-DR4, and have long-standing seropositive rheumatoid arthritis complicated by erosive joint disease, subcutaneous nodules, and/or leg ulcers. The natural history is often marked by repeated infection with 5-year mortality rates in some studies of > 30%. The complex pathophysiology is discussed in Chapter 52.

T-LARGE GRANULAR LYMPHOCYTE (T-LGL) LEUKEMIA^{19, 20}

LGL are medium to large lymphocytes recognizable on light microscopy by their distinctive azurophilic granules (Fig. 62.2). These normally constitute less than 15% of circulating leukocytes and are composed of two major subsets. One population, natural killer (NK) LGLs, expresses

Fig. 62.2 The large granular lymphocyte (LGL) is a moderate-sized lymphocyte containing several distinctive azurophilic granules. Additional immunophenotyping is required to distinguish the CD3⁺, CD8⁺, CD57⁺ T-LGL associated with neutropenia from CD16⁺, CD56⁺ natural killer (NK)-LGL.

CD2, CD16, and CD56, and are not linked to neutropenia. The other, T-LGLs, expresses CD2, CD3, CD8, and CD57 with or without CD16, a phenotype typical of antigen-stimulated mature CD8 effector T cells. Polyclonal and transient monoclonal expansions of these cells sometimes appear in response to viral infection or other immune stimuli without adverse effect. However, some patients develop an indolent lymphoproliferative disease characterized by the accumulation of an autonomous T-LGL clone in the blood and in other lymphoid organs, particularly the bone marrow, liver, and/or spleen. Patients with this disease have a remarkably high incidence of immune neutropenia.²⁰ Even in the absence of gross marrow replacement, over 80% have a neutrophil count of <2000/mm³ at presentation, and at some point 30–40% develop severe neutropenia with <500 neutrophils/mm³.^{19–21} The pathophysiology resembles Felty's syndrome in many respects.

NEUTROPENIA ASSOCIATED WITH SYSTEMIC AUTOIMMUNE OR LYMPHOPROLIFERATIVE DISEASES²²

Most patients with active systemic lupus erythematosus (SLE) develop neutropenia as part of a more global leukopenia (Chapter 51). Distinct from this, a smaller subset develops severe neutropenia, presumably mediated by anti-neutrophil antibodies. Sjögren syndrome (Chapter 54) and other systemic autoimmune diseases are also sometimes complicated by immune neutropenia. Lymphoproliferative disorders, such as chronic lymphocytic leukemia, rarely can be complicated by immune neutropenia as well.

DRUG-INDUCED IMMUNE NEUTROPENIA²³

A variety of medications cause neutropenia. In some cases it may be antibody-mediated (see Table 62.2 for common examples); in others it may be a direct toxic effect on marrow precursors. Often, the mechanism for neutropenia is unclear. A detailed discussion of this topic is beyond the scope of this chapter, but drug-induced neutropenia must always be considered in the differential diagnosis of acquired neutropenia. A list of the most common agents associated with drug-induced neutropenia is included in Table 62.2.

IMMUNOPATHOGENESIS

Regulation of anti-neutrophil antibody production

Isoimmune anti-neutrophil antibody production in pregnant women represents an 'appropriate' immune response to foreign antigens. The production of autoimmune anti-neutrophil antibodies in other settings reflects immune dysregulation. Older studies attributed primary immune neutropenia of childhood to delayed maturation of T cells responsible for regulating B-cell responses. In this view, the spontaneous recovery usually observed reflects the eventual appearance of mature suppressor T cells. This is a credible, if poorly documented, hypothesis. The cause of antibody production in other autoimmune diseases remains uncertain.

Antibody specificity

The most important target for antibody responses is the Fcγ receptor IIIb (FcγRIIIb), a low-avidity granulocyte-specific Fcγ receptor that binds IgG immune complexes (Fig. 62.3). This product, a glycosyl phosphatidylinositol-linked variant of CD16 selectively expressed on neutrophils, contains several highly immunogenic polymorphisms.²⁴

HNA-1a and HNA-1b (previously designated NA1 and NA2) are two related polymorphic forms of FcγRIIIb. Antigenic differences are attributed to a set of five closely linked base substitutions within exon 3. The two products can be distinguished based on size because two of the base substitutions in HNA-1a disrupt sites of *N*-linked glycosylation. The gene frequency of HNA-1a varies from 0.3 to 0.55 in different ethnic groups.

HNA-1c (previously designated SH) is another immunogenic polymorphism related to FcγRIIIb. This antigen, present in 5% of northern Europeans, is attributable to an amino acid polymorphism at position 266 in a reduplicated copy of the HNA-1b allele of FcγRIIIb.

FcγRIIIb-null phenotype, present in 0.1% of the northern European population, occurs in individuals homozygous for an extensive chromosomal deletion involving all of FcγRIIIb. Because affected individuals have never been exposed to endogenous FcγRIIIb, they often develop a broad antibody response after exposure through transfusion or pregnancy.

Other neutrophil antigens have also been identified. Perhaps most clinically relevant is HNA-2a, previously NB1, a neutrophil glycoprotein designated CD177. Antibodies against this target have been reported in isoimmune and autoimmune neutropenia. HNA-3a (previously 5b), and HNA-4a (previously MART), an epitope on CD11b, are also immunogenic, but antibody formation against these is seen primarily in heavily transfused individuals and not in autoimmune neutropenia. As described below, individuals with chronic immune neutropenia may develop antibodies against other surface antigens, including CD11b/CD18 and CD35.²⁵

Using a sophisticated antigen discovery strategy, patients with Felty's syndrome were found to have a high incidence of antibodies against an intracellular antigen eukaryotic elongation factor 1A-1 (eEF1A-1). Although the finding has been confirmed, this antibody probably does not play a crucial role in the pathophysiology of neutropenia since it is also present in nonneutropenic patients with autoimmune disease.

Detection of anti-neutrophil antibodies

Antibodies are assayed clinically using indirect assays, i.e., by measuring the binding of antibodies from patient sera to fixed granulocytes from unrelated individuals. The granulocyte immunofluorescence test (GIFT), which exploits flow cytometry for detection, is most commonly used because of its high sensitivity. The granulocyte agglutination test (GAT) is less sensitive but it is particularly valuable used in conjunction with GIFT to detect antibodies against HNA-3a or HNA-1b. Once the presence of an antibody has been confirmed, monoclonal antibody-specific immobilization of granulocyte antigens (MAIGA) is a valuable technique in identifying the target molecule recognized by the antibody, information which may be very helpful in identifying antibody specificity and in distinguishing granulocyte-specific antibodies from alloantibodies directed against HLA determinants. More precise epitope typing still requires a panel of granulocytes of varied phenotype. Unfortunately, to date, granulocyte panels are both difficult to prepare and impossible to store. Consequently, antibody typing remains a laborious, difficult task. At the second international granulocyte serology workshop, 12 centers independently tested a series of unknown sera. Many laboratories could detect strong HNA-1a antibodies, but the success rate was much lower in defining HNA-1b or HNA-2a antibodies, and individual laboratories varied greatly in their proficiency.²⁶

Patterns of antibody specificity

Isoimmune neonatal neutropenia

Maternal IgG iso or autoantibodies can be generated in response to each of the polymorphic alloantigens noted above, particularly polymorphisms affecting FcγRIIIb.

Immune neutropenia in childhood

Antibodies in these patients are IgG and most commonly directed against the autoantigens HNA-1a and/or HNA-1b.²⁵ Sera from affected patients often also bind (albeit more weakly) to neutrophils expressing the alternative allele, and in some series more than half the patients with this entity produce antibodies capable of binding to nonpolymorphic elements within FcγRIIIb. Using MAIGA to search for antibodies directed against other neutrophil surface molecules, more complex patterns can be recognized. In one study, autoantibodies against CD11b/CD18 (CR3) were seen in 21%, CD35 (CR1) in 14%, and FcγRII in 2% of patients.²⁷ Prognostically, patients with antibody responses confined to HNA-1a and/or HNA-1b are more likely to have uncomplicated, self-limited disease; patients with specificity for nonpolymorphic determinants on the FcγRIIIb molecule and other antigens more often have a generalized immune disorder and more persistent neutropenia.²⁵ Although

anti-neutrophil assays are not highly quantitative, a recent retrospective study suggests patients with low levels of anti-neutrophil antibodies may have a more favorable long-term prognosis.²⁸

Immune neutropenia in adults

It is often difficult clinically to distinguish immune from nonimmune idiopathic neutropenia in adults. Consequently, the sensitivity and specificity of antibody assays in this setting are uncertain. In general, antibody against HNA-1a or HNA-1b are less common, and antibodies against surface receptors such as CD11b/CD18 (CR3) are more common in older children and adults than in young children.

Felty's syndrome and T-LGL leukemia

Sera from patients with Felty's syndrome¹⁸ and T-LGL leukemia¹⁹ are often positive in anti-neutrophil antibody assays. Interpretation of these results is complicated by the high incidence of immune complexes in these populations, which may bind nonspecifically through Fc and complement receptors to the neutrophil surface. Indeed, because it is difficult to distinguish these two types of binding, the incidence of "true" anti-neutrophil antibodies in these syndromes remains uncertain. Where carefully studied, detectable anti-neutrophil antibodies are low in titer or absent in most patients with either diagnosis.^{18,19}

Impact of antibodies and immune complexes on neutrophil survival

There is sound experimental evidence that both anti-neutrophil antibodies and immune complexes can induce neutropenia *in vivo*. The relative importance of reversible sequestration and neutrophil destruction in inducing neutropenia varies with the experimental model, the character of the antibody/immune complex, spleen size, and presumably other factors as well.

The detection of anti-neutrophil antibodies in serum, however, does not automatically imply accelerated immune clearance of neutrophils *in vivo*. Some antibodies bind well to neutrophils under assay conditions, without provoking neutrophil destruction *in vivo*.²⁹ In part this reflects the inability of these crude assays to distinguish effective from ineffective binding of immunoproteins. For example, in attempts to correlate levels of allospecific anti-neutrophil antibody in serum from allosensitized individuals with neutrophil survival after transfusion, it was noted that antibodies capable of agglutinating neutrophils *in vitro* were associated with shortened neutrophil survival, but lymphocytotoxic or granulocytotoxic antibodies capable of promoting complement-mediated cytotoxicity did not. Clinical assays for detecting immune complexes share the same limitation.²² The impact of immune complexes on neutrophil sequestration varies markedly with the complex size, composition, and complement-fixing activity. Consequently, positive results in an anti-neutrophil antibody or immune complex assays may support, but do not prove, immune destruction is occurring *in vivo*. Because assay sensitivity is limited, a negative result reduces, but does not eliminate, the possibility of immune-mediated neutrophil clearance. In sum, anti-neutrophil antibodies and immune complexes can alter neutrophil trafficking and survival in the circulation, but our ability to predict this bioactivity prospectively is very limited.

THERAPEUTIC PRINCIPLES

- >> The palliative treatment of neutropenia is reserved for patients with a neutrophil count below $500/\text{mm}^3$ or recurrent infection
- >> Recombinant granulocyte- and granulocyte-macrophage colony-stimulating factor are the most effective single agents for palliating neutropenia
- >> Immunosuppressive agents, steroids, and splenectomy are reserved for patients with persistent or refractory neutropenia or with other detrimental manifestations of systemic autoimmunity

KEY CONCEPTS

- >> Immune neutropenia in children is caused by anti-neutrophil antibodies
- >> Immune neutropenia in adults has a more complex etiology
- >> Immune complex-mediated neutrophils clearance and cell-mediated suppression of myelopoiesis often play a major role

Myelopoiesis in immune neutropenia

In primary immune neutropenia the marrow is typically normocellular or mildly hypercellular with an increased proportion of early myeloid forms (particularly myelocytes and promyelocytes) and decreased mature forms (neutrophils, stabs, and metamyelocytes), a pattern designated maturation arrest. Although maturation arrest can also be seen in a number of other diseases, in this setting it suggests an expansion in immature precursors with early release of mature components into the blood. Rigorous kinetic studies in children with primary neutropenia are not available, but the available data suggest myelopoiesis in this setting is increased.

The findings are more complex in Felty's syndrome and T-LGL leukemia. *In vivo* neutrophil kinetic studies and *in vitro* assays of marrow function often document reduced myelopoiesis in these settings.^{18, 19} This has been attributed to T-cell- and cytokine-mediated suppression. T-LGL leukemia cells constitutively express Fas ligand on their surface and also release significant quantities into plasma *in vivo*. Reduced myelopoiesis in T-LGL leukemia and some patients with Felty's syndrome may be linked to apoptosis provoked by the binding of Fas ligand on the abnormal cells to Fas expressed on the surface of myeloid precursors.¹⁹ Whatever the precise mechanism, reductions in myelopoiesis appear to be a common element in patients with these forms of secondary immune neutropenia.

DIAGNOSIS

Clinical presentation

Isoimmune neutropenia presents at birth and may persist for up to 6 months. Self-limited primary autoimmune neutropenia typically presents in early childhood. In older children and adults, neutropenia is more

commonly associated with other systemic autoimmune disease, especially rheumatoid arthritis and SLE or T-LGL leukemia. Drug-induced neutropenia must always be considered in patients taking medications.

Since neutrophil destruction *per se* is clinically silent, patients often first seek medical attention because of bacterial infections, particularly involving the skin, upper respiratory tract, or middle ear. More serious systemic infections such as sepsis or meningitis are less common. Splenomegaly, skin lesions, and other manifestations of systemic autoimmunity are common in secondary variants, but not in the primary syndrome.

Laboratory findings

Blood counts typically demonstrate isolated neutropenia, sometimes with monocytosis. More generalized leukopenia, anemia, and/or thrombocytopenia should suggest concurrent SLE or a primary bone marrow disorder, especially aplastic anemia or myelodysplasia.

Examination of the blood film for evidence of abnormalities in other cell lines or increased numbers of LGL is essential. The persistent presence of >2000 LGL/ mm^3 for 6 months in itself is diagnostic of T-LGL leukemia; however, normal LGL counts in blood do not rule out this diagnosis. Perhaps a quarter of patients with T-LGL leukemia and immune neutropenia have fewer than 500 monoclonal LGL/ mm^3 in blood.¹⁹ The evaluation of patients with small T-LGL clones detected in blood on flow cytometric or molecular testing without clear tissue infiltration remains problematic. At least some of these patients probably have self-limited "T-cell gammopathies of unknown origin" unassociated with overt lymphoproliferation or autoimmunity.

Bone marrow findings in immune neutropenias (as briefly reviewed above) can vary substantially. Perhaps the most important function of the bone marrow exam is to rule out hypoplasia/aplasia, myelocathexis, marked megaloblastic dysplastic changes, or abnormal infiltration with nonhematopoietic cells, which might suggest an alternative diagnosis. The marrow exam may also be helpful in confirming T-LGL leukemia.³⁰

Clinical use of anti-neutrophil antibody studies

In young children with neutropenia, a positive result is very helpful in distinguishing between immune-mediated and congenital causes. Isoimmune and congenital disease may be apparent from birth and the former usually resolves within 2 months. Using GIFT or GAT assays, anti-neutrophil antibodies can be detected in more than 70% of children with primary immune neutropenia. When both are used in tandem the yield increases further. A strong positive result strongly supports the diagnosis of immune neutropenia. On the other hand, a negative study does not exclude the diagnosis.²⁸

Primary autoimmune neutropenia in adults is difficult to distinguish from the ill-defined entity chronic idiopathic neutropenia.¹ Since there is no "gold standard" for distinguishing immune from nonimmune disease in this setting, the diagnostic sensitivity and specificity of the anti-neutrophil antibody assays are unclear. Assays are positive in perhaps a third of adults referred with chronic neutropenia, and a positive result in the absence of other systemic autoimmune disease certainly supports a diagnosis of immune neutropenia. Again a negative result does not preclude an immune etiology, but it is more consistent with chronic idiopathic neutropenia.

In patients with systemic autoimmune disease or T-LGL leukemia, hyperglobulinemia and circulating immune complexes greatly complicate

laboratory evaluation. Anti-neutrophil assays are frequently positive even in the absence of neutropenia. Since the specificity of a positive result is low, its diagnostic value is very limited, and the clinician must be vigilant for other possible causes, especially drug-induced neutropenia.

Clinical overlap between Felty's syndrome and T-LGL leukemia

At the extremes these syndromes are easily separable. Patients with classical Felty's syndrome have severe rheumatoid arthritis, usually requiring anti-inflammatory therapy, incidentally complicated by late neutropenia. This is quite different from the pattern in patients with isolated T-LGL and neutropenia in the absence of clinical autoimmune disease.

Nonetheless, confusing overlap can occur in two settings:

1. More than half of patients with a clinical Felty's syndrome may have detectable T-LGL clones in their blood when studied with sensitive flow cytometric or molecular techniques.¹⁹ There have been attempts in the past to classify this pattern as pseudo-Felty's syndrome, but the clinical findings and course are often indistinguishable from "classical" Felty's syndrome.
2. About half of patients with clinically apparent T-LGL leukemia have circulating rheumatoid factor and immune complexes in their blood; about a third, usually patients expressing HLA-DR4, develop clinically significant arthritis sometimes requiring anti-inflammatory agents.

Although the reason why clonal T-LGL disorders and autoimmunity often coexist remains unclear, the tendency toward overlap is clear. Since the pathophysiology and therapy of both conditions are similar, these problems in classification usually have little impact on the initial management of neutropenia. When a patient with "Felty's syndrome" develops aggressive T-LGL leukemia, or a patient with T-LGL manifests severe rheumatologic symptoms, the clinician must be prepared to alter therapy as needed to fit the clinical picture.

While some have attempted to develop clinical criteria for distinguishing Felty's syndrome from T-LGL with pseudo-Felty's syndrome, there is now substantial evidence that clonal T-LGL are often present in rheumatology patients and that patients with clonal disorders seldom develop a progressive, neoplastic disorder. Conversely, although T-LGL leukemia patients have a malignancy, it is often extremely indolent. In these cases, the clinical course is often dominated by rheumatologic complication and/or neutropenia and not by progressive neoplastic disease.

THERAPY

Overview

All patients with neutrophil counts below 1000/mm³ have some increased risk of infection, but some remain asymptomatic even with absolute neutrophil counts of 500/mm³ or less. Growth factors can usually improve neutropenia and reduce the risk of infection, but given their expense, inconvenience, and possible side effects, they should be reserved for use in patients with a very low count, or a previous pattern of frequent infection. The indications for immunosuppressives, steroids, and splenectomy are more complex.

Colony-stimulating factors (CSF)

Controlled trials are lacking in this disease setting, but granulocyte-CSF (G-CSF) or granulocyte-macrophage-CSF (GM-CSF) usually enhance neutrophil counts in each of the clinical groups discussed. Because of their safety, speed, and efficacy, they have replaced steroids and splenectomy as first-line symptomatic therapy. They should be used at the lowest effective dose, with particular caution in patients with systemic autoimmune disease, who are prone to leukoclastic vasculitis as a complication of therapy.²²

Immunosuppressive agents

Because disease is usually self-limited and responsive to G-CSF, immunosuppressive agents are seldom used in children with primary immune neutropenia. Chronic low-dose oral therapy with methotrexate is often effective in treating neutropenia (and other autoimmune symptoms) in patients with Felty's syndrome and/or T-LGL. Cyclosporine is the preferred second-line therapy in T-LGL, and cyclophosphamide, cyclosporine, and gold are often considered second-line treatment for Felty's syndrome when total disease control is desired.

Steroids and splenectomy

Each of these treatments can be effective in reversing neutropenia, but their use has diminished considerably in recent years. Intravenous immunoglobulin (IVIG) can temporarily reverse neutropenia, particularly in children, probably by blocking Fc receptors responsible for triggering neutrophil destruction. However, G-CSF, which is more convenient to administer and at least as effective, has largely replaced this agent.

Splenectomy and steroids can each reduce immune destruction by suppressing the body's capacity to clear IgG- and complement-coated cells. Over a longer time frame these treatments may also suppress antibody production, in the first case by removing a major site of production, and in the second by reducing anti-neutrophil antibody production and blocking T-cell-mediated myelosuppression. They can reverse neutropenia in many patients, but their long-term impact on outcome remains unclear. Given their risk and side effects, both modalities are generally reserved for patients resistant to CSFs and low-dose immuno-suppressives.

Prophylactic antibiotics

Where recurrent infection is a problem, oral trimethoprim-sulfamethoxazole is commonly used for prophylaxis, particularly in children. This approach is very reasonable, given its success in other immunocompromised groups, but it has not been tested in a controlled trial.

IMMUNE THROMBOCYTOPENIAS AND COAGULATION INHIBITORS

Antibodies can cause destruction or dysfunction of platelets and coagulation factors as the primary manifestation of a disease, or they may be part of an immune disorder that stimulates a spectrum of antibodies causing multiple symptoms in the patient. Antibodies against platelets may cause profound thrombocytopenia as a result of increased platelet clearance or through decreased platelet production when antibodies reduce megakaryocyte production and maturation.³¹ They can also alter

Fig. 62.3 Platelets with bound antibody are cleared from the circulation by the binding of the antibodies to FcγRIIA receptors on macrophages and other cells. The cross-linking of the macrophage receptors sets off a cascade of internal signaling that leads to increased expression of the inhibitory FcγRIIB receptors (not shown).

platelet function by binding to platelet surface proteins necessary for hemostasis. Antibodies directed against coagulation factors or phospholipid coagulation factor complexes can inhibit their function or mediate their clearance from the circulation, causing a bleeding diathesis. One class of antibodies, the lupus anti-coagulants (LAC), predisposes to thrombosis.

IMMUNE THROMBOCYTOPENIC PURPURA (ITP)

Pathogenesis

ITP, also called idiopathic or autoimmune thrombocytopenic purpura, is a diagnosis of exclusion and is caused by autoantibodies that promote increased platelet clearance and may decrease platelet production. The stimulus for this autoantibody production is unknown; however, it has been demonstrated that antibody-coated platelets are removed from the circulation through an Fcγ receptor-dependent mechanism,³² and that T-cell abnormalities are also important in ITP.³³ Antibodies specific for several platelet surface and megakaryocytic proteins have been detected in patients with ITP.³⁴

Both activating and inhibiting Fc receptors on cells are important in the platelet destruction of ITP. Murine models have shown that agents that are used therapeutically in humans with ITP, IVIG and anti-D, decrease the removal of antibody-coated platelets either by increasing the expression of the inhibitory FcγIIB receptor (CD32),³⁵ or by decreasing the expression of a different Fcγ receptor, activating FcγIIIA (CD16).³⁶ Specific FcγIIIA receptor blockade using a murine antibody has been successful in transiently increasing the platelet count in ITP patients, but this treatment could not be continued because of the formation of human–antimouse antibodies.³⁷

Diagnosis and clinical course

The diagnosis of ITP is based on history, physical examination, complete blood count, examination of the peripheral smear, and review of the patient's medications and exposures.³⁸ The diagnosis is established when a patient has isolated thrombocytopenia without other causes and in whom the bleeding symptoms are consistent with the decrease in platelet numbers. The low sensitivity of current assays for platelet antibodies and

KEY CONCEPTS

IMMUNE THROMBOCYTOPENIC PURPURA

- >> Both B and T cells important in etiology
- >> Clearance of platelets mediated by Fc receptors
- >> Diagnosis depends on:
 - >> Clinical presentation of low platelets
 - >> Exclusion of other causes of thrombocytopenia

the technical difficulty in performing them limit their clinical use as a diagnostic criterion for ITP; they detect antibodies in 31–88% of patients.^{39,40} ITP in children often occurs after a viral illness and usually follows a course with spontaneous recovery occurring within months; it is generally a less serious illness than adult ITP.^{32,38} ITP in adults most often follows a chronic course with few spontaneous remissions. The diagnosis is strengthened when a patient has a good response to treatment with immunosuppressive medications such as IVIG or prednisone. A bone marrow examination may be appropriate in certain situations, such as in elderly patients where underlying myelodysplasia or lymphoproliferative disease may be suspected, prior to splenectomy, in patients who are unresponsive to immunosuppressive medications, and when other unexplained cytopenias are present.

In children, persistent thrombocytopenia may indicate a congenital disorder, and factors that point to a congenital platelet disorder include abnormalities in platelet size, high-frequency hearing loss, congenital anomalies, and renal function abnormalities. Bleeding out of proportion to the thrombocytopenia may indicate type 2B von Willebrand disease. Human immunodeficiency virus (HIV) testing is important because treatment of HIV may improve an associated immune thrombocytopenia. Review of the patient's medications is also important to exclude drug-induced thrombocytopenia, and in certain populations testing for *Helicobacter pylori* may be indicated. Remissions after treatment of the bacterium have been reported in Italy and Japan, but unfortunately results have been less impressive in the USA.⁴⁰

Treatment

The primary goal in the treatment of patients with ITP is to prevent bleeding. Treatment must be individualized, taking into account the level of activity of the patient's lifestyle, the presenting platelet count, and whether signs of bleeding are present. Usually patients with platelet counts of 30 000/μl or greater do not have significant bleeding, and treatment may be deferred.^{32,38,40} For a patient with severe thrombocytopenia (<20 000/μl) or bleeding that requires immediate treatment, IVIG and prednisone are usually the treatments of choice.^{32,38,40} Platelet transfusions and/or plasmapheresis are added to the regimen if the bleeding is life-threatening. For patients with less serious bleeding who require treatment, prednisone (1 mg/kg) is usually given for 2–4 weeks or until a response occurs; it is then slowly tapered, at about 3-week intervals, with monitoring of the platelet counts. For patients who continue to have persistent severe thrombocytopenia (<30 000/μl) or whose platelet counts

drop to unacceptable levels during the tapering of steroids, splenectomy is usually the treatment of choice. Complete responses occur in about two-thirds of patients after splenectomy.⁴¹ Patients should receive immunizations with the pneumococcal, *Hemophilus influenzae* b, and the quadrivalent meningococcal vaccines prior to splenectomy.³⁸ In some patients who are stable with a platelet count of $<30\,000/\mu\text{l}$, splenectomy is deferred and a more prolonged trial of anti-D or anti-CD20 therapy (rituximab) is given.⁴⁰ The latter therapy is not approved by the US Food and Drug Administration for ITP; however rituximab resulted in response rates of greater than 30% in phase II clinical trials.⁴²

Therapy for chronic severe ITP that is refractory to splenectomy can be challenging. The primary goal continues to be the prevention of bleeding, and this must be balanced by the potential long-term side effects of different therapies. Anti-CD20 treatment can be used after splenectomy in addition to steroid-sparing agents that include mycophenolate mofetil, danazol, and cyclosporine. If these are not successful, other therapeutic agents utilized are azathioprine, low-dose cyclophosphamide, and vincristine. Adjunctive therapy with antifibrinolytic agents such as ϵ -aminocaproic acid can help decrease mucosal bleeding. Higher-risk therapy includes combination chemotherapy or high-dose cyclophosphamide with autologous stem cell rescue.^{38,40,43} These options should be reserved for patients with severe thrombocytopenia who have bleeding symptoms and have failed more conservative therapy. A new approach showing some efficacy in preliminary clinical trials is the use of thrombopoietic factors⁴⁰; the use of recombinant activated factor VII needs to be studied for efficacy for severe bleeding episodes in ITP patients.

ITP during pregnancy and the neonatal period

Immune thrombocytopenia should be distinguished from other causes of thrombocytopenia during pregnancy such as benign gestational thrombocytopenia, disseminated intravascular coagulation, hemolysis, elevated liver enzymes, and low platelet count (HELLP) syndrome, thrombotic thrombocytopenic purpura, and the acute fatty liver of pregnancy. ITP is more likely when there is a previous diagnosis of ITP, with early presentation during pregnancy, and with profound thrombocytopenia ($<50\,000/\mu\text{l}$). In general, women with a platelet count of greater than $50\,000/\mu\text{l}$ should not be treated because of the potential deleterious effects

of corticosteroids to the mother and the fetus.³⁸ IVIG is often effective in temporarily increasing platelet counts, and it is useful prior to delivery or epidural anesthesia.

About 4% of infants born to mothers with ITP will have severe thrombocytopenia; fortunately, the danger of intracerebral hemorrhage is low in these infants. Previous neonatal outcomes are the best predictor of the risk during future pregnancies.⁴⁰ Platelet counts should be monitored for at least 4 days after birth because platelet count nadirs can be delayed in these neonates.³⁸ If the infant's platelet count is less than $50\,000/\mu\text{l}$, brain imaging should be obtained to rule out hemorrhage.^{38,40} Treatment with IVIG and prednisone is administered if the platelet count is less than $20\,000/\mu\text{l}$, or if there is bleeding regardless of the platelet count.

NEONATAL ALLOIMMUNE THROMBOCYTOPENIA AND POSTTRANSFUSION PURPURA

Neonatal alloimmune thrombocytopenia is caused by maternal antibodies against human platelet antigens that the fetus carries, but that the mother lacks (most commonly human platelet antigen-1a (PLA-1)). It is more likely to cause intracerebral hemorrhage (10–20% of cases) compared with children born to mothers with ITP, and it is very likely to recur if it has occurred in a previous pregnancy.⁴⁴ IVIG and platelet transfusions using maternal platelets (to insure that the offending antigen is not present in the transfused product) are often necessary.

Antibodies against human platelet antigens are also responsible for posttransfusion purpura, in which the recipient has an acquired antibody directed against a platelet antigen on the donor platelets. For reasons not entirely understood, the antibodies also destroy the patient's own "antigen-negative" platelets. Treatment consists of IVIG and corticosteroids and sometimes plasma exchange.⁴⁵

DRUG-INDUCED THROMBOCYTOPENIA

Drugs can cause thrombocytopenia through multiple mechanisms. They may decrease platelet production, or cause peripheral destruction by stimulating antibody formation:

- A platelet epitope may be altered by the binding of drug to the platelet.
- A neoantigen may be created by the formation of an epitope consisting of the drug-membrane complex (hapten).
- The drug itself may be antigenic, and antibody plus the drug may form an immune complex that binds to platelets by Fc receptors.⁴⁶

If a drug is suspected of causing immune thrombocytopenia, it should be discontinued and the platelet count followed. If the patient has bleeding, platelet transfusions are administered. The platelet count usually recovers in about 5–7 days. Among the common drugs that may cause thrombocytopenia by antibody destruction are penicillin, sulfonamides, gold salts, and anti-seizure medications such as phenytoin.⁴⁷

Heparin-induced thrombocytopenia (HIT), which is caused by antibodies to platelet factor 4 (PF4)-heparin complex, is a special case that can be associated with life-threatening thrombosis. The antibody-PF4-heparin complex activates platelets, resulting in a high risk of both arterial and venous thrombotic events.⁴⁸ Thrombocytopenia occurs due to clearance of platelet aggregates caused by the antibody and usually appears 5–7 days after treatment with heparin (or low-molecular-weight heparin) unless a patient has been exposed to heparin in the past 100 days. In this instance, thrombocytopenia can occur within 1 day of heparin

THERAPEUTIC PRINCIPLES

IMMUNE THROMBOCYTOPENIC PURPURA (ITP)

- >> Primary goal – prevent bleeding
- >> Treatment not usually necessary if platelets $>30\,000/\mu\text{l}$

administration. Even small doses of heparin given as “flushes” to maintain intravenous catheter patency can be sufficient to cause HIT. In cases of suspected HIT, all heparins should be stopped and an alternative anti-coagulant agent should be used, such as the direct thrombin inhibitors argatroban and lepirudin. Fondaparinux is a pentasaccharide anti-coagulant that may become a third option for treatment of HIT. In cases of confirmed or strongly suspected HIT, anti-coagulation should be continued for 3 months because the risk of thrombosis persists in this group of patients. Coumadin is generally used for long-term anti-coagulation; it should be started by overlapping with one of the agents above because of the increased risk of thrombosis due to the initial depletion of anti-coagulant factors (proteins C and S).

ANTIBODIES TO COAGULATION FACTORS

Antibodies to coagulation factors arise most frequently in patients who have a hereditary deficiency of a factor and receive replacement therapy (alloantibodies); others arise spontaneously as autoantibodies, most commonly to factor VIII (anti-hemophilic factor). Serious bleeding can result in both instances. In contrast, the most common acquired anti-coagulant, the lupus anti-coagulant (LAC), predisposes to thrombosis.

LUPUS ANTI-COAGULANTS

LACs are autoantibodies that target proteins bound to phospholipid, usually β_2 -glycoprotein I or prothrombin (Fig. 62.4); they are defined in the laboratory by a prolongation of phospholipid-dependent steps in the coagulation cascade.⁴⁹ LACs and/or anti-cardiolipin antibodies (antibodies defined by enzyme-linked immunosorbent assay testing), along with clinical symptoms of venous or arterial thrombosis or recurrent pregnancy morbidity, comprise the anti-phospholipid syndrome (APS). APS is a thrombotic syndrome that is most common in women and often occurs in individuals with autoimmune diseases such as SLE, but also occurs in other inflammatory conditions or infections (Chapters 51 and 61). Besides recurrent venous and/or arterial thrombosis and fetal loss,

the syndrome may include thrombocytopenia, autoimmune hemolytic anemia, livido reticularis, cardiac valve disease (Libman–Sacks), and central nervous system manifestations including headache, seizure, and stroke. The mechanisms by which these antibodies lead to thrombosis are not fully defined, but specific causes include antibody activation of endothelial cells and platelets, inhibition of fibrinolysis, inhibition of activation of the natural anti-coagulant protein C, disruption of annexin V binding to cell surfaces (allowing coagulation factors access to cell surface phospholipid and to possible activation), and inhibition of the natural anti-coagulant action of β_2 -glycoprotein I which normally prevents binding of von Willebrand factor to its platelet receptor.

The diagnosis is established when a clotting test that requires phospholipid to create a fibrin clot is prolonged and

- is not “corrected” by a 1:1 mixing study with normal plasma
- but is corrected by the addition of excess phospholipid.⁵⁰

In practice, the partial thromboplastin time is the most commonly performed test that initially detects a LAC, so a LAC may be discovered during routine coagulation screening prior to invasive procedures or during a medical evaluation. Several more specific assays are available to detect LACs, and at least two different assays should be performed if suspicion of a LAC is high, since one test may be negative and others may be positive. The tests indicate a LAC when the abnormal clotting time in the assay is “corrected” during a second assay in which extra phospholipid is added. If correction is not present with the added phospholipid, the test is negative for a LAC. Since these antibodies can be transient, they or anti-cardiolipin antibodies must remain positive for longer than 12 weeks (along with the history of thrombosis and/or pregnancy morbidity) to allow the diagnosis of APS.

Treatment is not indicated for a positive test alone. Treatment for acute thrombosis in patients who have APS consists of routine anti-coagulation starting with heparin and followed by coumadin for at least 6 months. Treatment is prolonged if the thrombosis has occurred in an unusual site such as a mesenteric or hepatic artery or vein or has resulted in a major pulmonary embolus. When patients with LACs have more than one thrombotic episode, lifelong anti-coagulation is usually prescribed unless the patient has a high risk of bleeding. Pregnancy morbidity is treated with heparin (unfractionated, subcutaneously, or low-molecular-weight heparin) and low-dose aspirin.

FACTOR VIII INHIBITORS

Antibodies to factor VIII occur in up to 30% of severe hemophiliacs as a result of exposure to factor VIII replacement therapy.⁵¹ They are IgG antibodies, often of the IgG₄ subclass. The antibodies greatly complicate

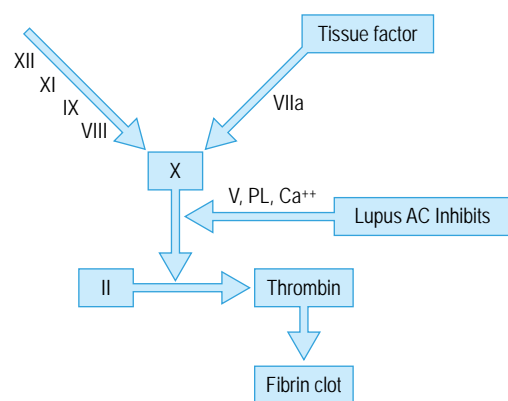

Fig. 62.4 Lupus anti-coagulants inhibit the coagulation cascade assays by interfering with the activation of prothrombin (factor II) to thrombin. This step requires phospholipid (PL) along with the other cofactors, factor V and ionized calcium (Ca^{++}).

KEY CONCEPTS

LUPUS ANTICOAGULANTS

- >> Antibody(ies) versus protein–phospholipid complexes
- >> Diagnosis based on phospholipid-dependent clotting tests
- >> May cause serious arterial or venous thrombosis
- >> Does not cause bleeding; other associated antibodies may cause bleeding

therapy, since they inhibit factor VIII that would normally be given to prevent or stop bleeding. Inhibitors are suspected when a patient does not respond to usual factor VIII replacement therapy. They are confirmed by detecting a shortened factor half-life after replacement and by a factor VIII inhibitor assay. The inhibitor assay uses a mixture of patient plasma (as the source of antibody) and normal pooled plasma (as the source of factor VIII) in 1:1 proportions; after incubation, the mixture is assayed for residual factor VIII activity and the antibody is quantified in Bethesda units. One unit of inhibitor is the quantity of antibody that inhibits 50% of the factor VIII in the normal plasma pool after 2–4 hours' incubation at 37°C. Usually several dilutions of the patient plasma containing the antibody must be incubated with normal plasma to determine the amount of antibody that will inhibit 50% of the factor VIII in the normal plasma; the units of inhibitor are the inverse of the dilution that inhibits 50% of starting factor VIII activity.

Acquired inhibitors to factor VIII are rare, estimated to affect 1 in 2 million individuals; fatal outcomes, however, are reported in up to 20% of patients.⁵² Bleeding often occurs in soft-tissue, retroperitoneal, genitourinary, or gastrointestinal sites rather than in joints. These antibodies can be associated with allergic drug reactions, malignancies, autoimmune diseases, and the postpartum state, or they may appear spontaneously. Diagnosis is made in the laboratory with a prolonged activated partial thromboplastin time and a low factor VIII, a positive factor VIII inhibitor assay.

Treatment for bleeding episodes in patients who have inhibitors to factor VIII may include very high doses of factor VIII concentrates (if the inhibitor titer is <5 Bethesda units), porcine factor VIII, recombinant human factor VIIa, and prothrombin complex concentrates that bypass the step requiring factor VIII during fibrin formation.⁵² Plasmapheresis is also used to remove the inhibitor temporarily in serious bleeding situations. To decrease antibody production, prednisone, cyclophosphamide, azathioprine, IVIG, cyclosporine, and, more recently rituximab, are used. Individuals with acquired inhibitors usually respond within 3–8 months. In hemophilic patients who have inhibitors, immune tolerance regimens that include daily or less frequent injections of factor VIII are utilized for long-term treatment; these patients may require over 12 months of therapy.

THERAPEUTIC PRINCIPLES

FACTOR VIII (FVIII) INHIBITORS

- >> For acute bleeding episodes for FVIII inhibitors:
- >> FVIII concentrates if inhibitor <5 Bethesda units
- >> Recombinant FVIIa or prothrombin complex concentrations for inhibitor titers >5 Bethesda units
- >> For chronic persistent inhibitors in hemophilia A patients with inhibitors:
 - >> Immune tolerance regimens
- >> Acquired inhibitor patients:
 - >> Immunosuppressive medications

INHIBITORS TO OTHER COAGULATION FACTORS

Antibodies to von Willebrand factor (VWF) can lead to mucocutaneous bleeding, including gastrointestinal bleeding.⁵³ Although rare, they occur in conjunction with autoimmune, lymphoproliferative, and myeloproliferative diseases as well as other illnesses. Although VWF and factor VIII levels are decreased in these patients, the antibodies are notoriously difficult to demonstrate *in vitro*, in some cases because they cause immune complexes of antibody-VWF which are cleared from the circulation, thereby lowering the VWF level. The diagnosis is made in a patient who lacks a past personal and family history of bleeding and has decreased VWF and factor VIII levels. These patients often respond to treatment with IVIG or desmopressin (desmopressin releases VWF and factor VIII from body storage sites). Factor VIII/VWF concentrates may be administered if the response is not adequate.

Acquired antibodies to other coagulation factors are also rare.⁵² They are usually detected in a patient who presents with a bleeding diathesis and is found to have an abnormal clotting test that does not "correct" to normal in a 1:1 mixing study with pooled normal plasma. Further testing reveals which factor is decreased, and an inhibitor assay shows the presence of an antibody inhibitor. A specific antibody to prothrombin, which causes clearance of the factor, is found in about 5–10% of patients with LACs; this is a separate antibody from the LAC, and it may cause significant bleeding. Patients with acquired inhibitors may respond to replacement therapy using a specific factor concentrate or fresh frozen plasma; they may also require immunosuppressive therapy to abolish the inhibitor.

Bullous diseases of the skin and mucous membranes

Khaled M. Hassan, Russell P. Hall III

63

PEMPHIGUS

Pemphigus is the term used to describe a group of diseases that have in common superficial blistering of the skin and mucous membranes. Pemphigus can be separated into four distinct groups: pemphigus vulgaris (PV), pemphigus foliaceus (PF), paraneoplastic pemphigus, and intraepidermal immunoglobulin A (IgA) neutrophilic dermatosis.

PEMPHIGUS VULGARIS

PV is the most severe form of pemphigus. PV presents most often in the fourth to sixth decades, but has been reported to occur at any age. Clinically, patients with PV are characterized by the presence of flaccid blisters and erosions of the skin and mucous membranes. Virtually all patients with PV will develop oral erosions at some point during the course of their disease. Most present with oral erosions and many have oral erosions as their only disease manifestation for months to years. These lesions are often persistent, shaggy erosions that can involve all areas of the oral mucosa, extending into the esophagus. In severe cases other mucous membranes, such as the conjunctiva, nasal, anal, cervical, or urethral mucosa, can also be affected.

The blisters seen in patients with PV are flaccid, easily ruptured, and can occur on either inflamed or noninflamed skin. The ease with which these blisters rupture is the origin of the Nikolsky sign, which is elicited

when lateral traction on the skin results in desquamation of the superficial layer of the skin. This sign, although helpful, is not unique to PV. Once broken these blisters leave large, nonhealing erosions. Blisters can occur on any area of the skin, most often beginning on the head and neck or trunk. Generalized blistering is not uncommon, especially if diagnosis and/or treatment has been delayed.

Pemphigus vegetans is an unusual variant of PV in which lesions develop that are localized primarily to the axilla, groin, and other flexural areas. The lesions are characterized as hypertrophic granulation tissue with occasional pustules. This presentation can occur *de novo* or after healing of PV lesions. The etiology of this unusual clinical presentation is not known.

Before the advent of systemic glucocorticoid therapy, PV was almost uniformly fatal, with patients developing large areas of denuded skin and dying from overwhelming sepsis. Since the introduction of systemic glucocorticoids the mortality rate has fallen to approximately 10%. The residual mortality is due in large part to side effects of the high doses of systemic glucocorticoids required to treat the disease, particularly in debilitated or elderly patients.

Histologically, PV is characterized by the presence of an intraepithelial blister, with acantholysis or breaking apart of the suprabasilar portion of the epidermis. Biopsy of an early lesion of PV reveals that the basal cells of the epidermis remain attached to the dermis, forming a 'row of tombstones,' with loss of attachment of individual keratinocytes to each other, resulting in the formation of an intraepidermal blister.

A major advance in the understanding of PV occurred in the early 1960s, when Beutner and co-workers described IgG antibodies bound to the epithelial keratinocyte cell surface in the skin of patients with PV.¹ They also demonstrated that the serum of patients with PV had IgG antibodies that bound in an identical pattern to normal human skin *in vitro*.² These findings demonstrated that PV is an autoimmune disease directed against a normal component of stratified squamous epithelium.

PEMPHIGUS FOLIACEUS

PF is characterized by blisters within the epidermis, resulting in the development of superficial erosions with scaling and crusting (Fig. 63.1). Unlike patients with PV, those with PF rarely develop mucous membrane

KEY CONCEPTS

PEMPHIGUS VULGARIS

- >> Flaccid blisters with denuded epidermis
- >> Oral mucous membrane lesions common
- >> Suprabasilar blister with 'row of tombstones'
- >> Immunoglobulin G deposits on keratinocyte cell surface (antigenic target = desmoglein-3)

lesions. Because of the superficial nature of the blister many patients present with only erythematous, scaling, and crusted plaques on the head, neck, and trunk. The prognosis for patients with PF is markedly better than for those with PV, although patients with severe disease do occasionally die, usually as a result of infectious complications of the disease and/or therapy. The better prognosis is likely secondary to the more superficial nature of the blistering process.

An unusual variant of PF is the endemic form of the disease, *fogo selvagem* (Portuguese for 'wild fire').³ This is identical to the sporadic form of PF but is endemic to certain rural areas of South America. The epidemiology suggests an infectious etiology, and preliminary data suggest that an arthropod vector may be involved in spreading the disease.

Pemphigus erythematosus, or Senear–Usher syndrome, is another variant of PF. These patients have typical features of PF with additional characteristics suggestive of systemic lupus erythematosus. The clinical course tends to parallel that of PF, and most patients do not develop systemic lupus erythematosus. The pathogenesis of this form of PF is poorly understood.

Fig. 63.1 Patient with pemphigus foliaceus showing superficial erosions and crust formation on the head and neck.

KEY CONCEPTS

PEMPHIGUS FOLIACEUS

- >> Flaccid blisters with scale and crust
- >> Oral mucous membrane lesions rare
- >> Intraepidermal blister, granular cell layer
- >> Immunoglobulin G deposits on keratinocyte cell surface (antigenic target = desmoglein-1)

PF can also be associated with drugs. The most common agents that induce pemphigus are D-penicillamine and captopril, or other angiotensin-converting enzyme inhibitors.⁴ Although these drugs may induce a PV-like picture, the clinical manifestations are most often similar to those of PF. Patients with drug-induced pemphigus have autoantibodies directed against the keratinocyte cell surface but the pathogenetic mechanisms that lead to formation of these antibodies are unknown. It has been postulated that reactive sulfhydryl or amide groups, common to many of the drugs that are associated with drug-induced pemphigus, may be important elements in this reaction.⁴

The histology of a PF blister reveals a superficial, intraepidermal blister with acantholysis of only the most superficial portion of the skin. This blistering occurs in the region of the granular cell layer of the skin, with the result that blisters have a base of epithelium and not the single basal cell layer that is seen in patients with PV.

The immunohistologic features of PF observed are indistinguishable from those seen in PV (Fig. 63.2). Cell surface deposits of IgG are seen in the skin of patients with PF, and circulating IgG, which binds to normal stratified squamous epithelium, is present in the serum of patients with PF.³ Although the immunofluorescence patterns are virtually identical between PF and PV, the antigenic targets of these autoantibodies are different, as discussed below.

PARANEOPLASTIC PEMPHIGUS

Anhalt described occasional patients who presented with a heterogeneous picture of severe oral erosions and polymorphic skin lesions suggestive of both PV and erythema multiforme.⁵ In each case the patients had an associated malignancy, generally lymphoreticular and including lymphoma, chronic lymphocytic leukemia, or thymomas. The histologic features of the skin lesions in these patients resembled those of PV, including suprabasilar blister formation with the additional finding of keratinocyte cell necrosis, as seen in erythema multiforme. The immunopathology of skin biopsies from these patients revealed IgG bound to keratinocyte cell surfaces, and granular-linear deposits of IgG and C3 at the basement membrane. In addition, the serum of these patients contained circulating IgG antibodies, which bound to normal keratinocyte cell surfaces of squamous epithelium. Although initial reports suggested that this antibody bound to both nonstratified and

Fig. 63.2 Direct immunofluorescence of perilesional normal-appearing skin from a patient with pemphigus foliaceus using antibodies directed against human immunoglobulin G (IgG). Cell surface IgG deposits are seen on the epidermal keratinocytes. A similar pattern is seen in patients with pemphigus vulgaris.

stratified squamous epithelium, this is not always the case. The antigenic targets of these antibodies are also distinct from both PV and PF, as discussed later.

INTRAEPIDERMAL NEUTROPHILIC IgA DERMATOSIS

In 1985, a patient with an annular, vesiculopustular eruption characterized by intraepidermal blisters with numerous polymorphonuclear leukocytes (PMN) and intercellular deposits of IgA on direct immunofluorescence staining was described by Huff et al., who proposed the name intraepidermal neutrophilic IgA dermatosis.⁶ This entity has subsequently been described by other investigators and has been referred to by several different names, including IgA pemphigus, intercellular IgA vesiculopustular dermatosis, and intercellular IgA dermatosis.

Patients with this disorder present with a heterogeneous clinical picture. Some present with tense blisters that enlarge peripherally to form a flower-like grouping, whereas others present with superficial pustules, erosions, and crusts. Sites of involvement include the trunk, abdomen, face, scalp, and extremities, but mucosal involvement has not been reported. Routine histology of lesional skin reveals the presence of either a subcorneal or an intraepidermal blister, with acantholytic cells and a polymorphous infiltrate marked by the predominance of PMN.

Direct immunofluorescence of perilesional skin biopsies from these patients shows IgA deposits on the keratinocyte cell surface. These deposits have been localized to the lower two-thirds of the epidermis in a subset of patients with a subcorneal pustular dermatosis-like disease. Approximately half of these patients have detectable, but low-titer, circulating IgA antibodies specific for epithelium.⁶

PATHOGENESIS

The antigenic targets in pemphigus have been defined as different components of desmosomes, key structures involved in keratinocyte adhesion (Table 63.1). IgG from patients with PF binds to a 160-kDa glycoprotein, desmoglein-1. IgG from patients with PV with only mucosal lesions binds predominantly to a distinct 130-kDa glycoprotein, desmoglein-3, a unique epithelial cadherin with significant homology to desmoglein-1. PV patients with both skin and mucosal disease have IgG antibodies directed against both desmoglein-1 and desmoglein-3.⁷

In paraneoplastic pemphigus, IgG antibodies have been shown to bind to members of the plakin family of desmosomal/hemidesmosomal proteins (desmoplakin I, II, envoplakin, periplakin, plectin, BPAG1) as well as to desmogleins-1 and -3.⁵

Sera from patients with intraepidermal IgA neutrophilic dermatosis have also been used to determine the antigenic targets relevant for this disease. Serum from a patient with the intraepidermal neutrophilic variant recognized a 120-kDa protein from extracts of normal human skin and bovine desmosomes.⁸ In contrast, sera from patients with subcorneal pustular dermatosis-like disease recognized proteins in a bovine desmosomal extract that were identified as the desmosomal proteins desmocollin I and II.⁸

In addition to the identification of the specific antigens against which the IgG from patients with pemphigus react, it has been clearly demonstrated that these antibodies are pathogenic. Anhalt and co-workers developed an animal model that demonstrated the pathogenicity of the autoantibodies found in many forms of pemphigus.⁹ In this model,

neonatal mice injected with IgG from patients with pemphigus developed cutaneous blisters, histologic changes and immunofluorescence findings consistent with pemphigus. This has been shown with sera from patients with PV, PF, and paraneoplastic pemphigus.^{5,9}

The factors that lead to the development of the autoimmune response are not known. Various investigators have demonstrated an increased frequency of human leukocyte antigen (HLA)-DR4 and HLA-DR6 in patients with PV.¹⁰ Healthy relatives of patients with PV were also shown to have low levels of autoantibodies directed against an epidermal antigen similar to the PV antigen, and the presence of these antibodies was associated with HLA-DR4 or -DR6.^{10,11} Additional studies showed that a specific HLA-DR4 subtype (DRB1*0402) is associated with PV.¹² This DR4 subtype is distinct from those DR4 molecules associated with rheumatoid arthritis (Chapter 52). Studies also showed that T cells from patients with PV secreted high levels of interleukin (IL)-4 and IL-10 in response to specific desmoglein-3 peptides when presented by DRB1*0402.¹² Other workers have further demonstrated that T cells reactive against desmoglein-3 are present in patients with PV, and that T cells from some normal HLA DRB1*0402 subjects also responded to desmoglein-3.¹³ It remains unclear what additional factors are required for HLA-susceptible individuals to develop clinical disease, but additional susceptibility genes and/or environmental factors are probably critical for disease development.

Fogo selvagem, a form of PF endemic to certain regions of Brazil, is also associated with particular HLA-DRB1 alleles (DRB1*1042, *1406 and *0404).^{14,15} The prevalence of antibodies against desmoglein-1 is high among normal subjects living in areas where fogo selvagem is endemic, and the onset of disease is preceded by a sustained antibody response.³ Fogo selvagem has been associated with exposure to the hematophagous black flies found in the endemic areas of Brazil. It has been suggested that the development of fogo selvagem may be related to an immune response to the bite of this fly in the HLA-susceptible individuals who develop cross-reactive antibodies against desmoglein-1.

Despite the clearly demonstrated importance of autoantibodies in disease pathogenesis, the exact mechanism by which they cause acantholysis is not known. Complement components (C3, C1q) are often present in the lesional skin of patients with pemphigus but these autoantibodies can induce acantholysis both *in vitro* and in the neonatal mouse model without complement activation.¹⁶ In total, these data suggest that, whereas complement may play a role in acantholysis, especially in an additive fashion, pemphigus IgG by itself can attach to the keratinocyte and induce the characteristic loss of cell-cell adhesion. Although early reports suggested that urokinase plasminogen activator was necessary for the development of skin lesions, pemphigus antibodies have been shown to be pathogenic in plasminogen-activator knockout mice.¹⁷ Recent evidence suggests that acantholysis in pemphigus may be related to the intracellular signaling that occurs after the binding of pemphigus antibody to cell surface desmogleins,¹⁸ with inhibition of p38MAPK preventing disease in the mouse model.¹⁹

THERAPY

Before the advent of systemic glucocorticoids, pemphigus was uniformly fatal. The introduction of high-dose systemic glucocorticoids and improvements in wound care have markedly reduced PV mortality but it remains a serious condition. Most blistering can be controlled with prednisone 1–2 mg/kg per day, usually in divided doses, and the dose can be

Table 63.1 Immunopathology of autoimmune blistering diseases

Disease	Direct IF (patient's skin)	Indirect IF (patient's serum)	Antigen(s)
Pemphigus vulgaris	IgG keratinocyte cell surface	IgG binds keratinocyte cell surface (normal stratified squamous epithelium)	Desmoglein-3 (DSG3) +/- Desmoglein-1 (DSG1)
Pemphigus foliaceus	IgG keratinocyte cell surface	IgG binds keratinocyte cell surface (normal stratified squamous epithelium)	Desmoglein-1 (DSG1)
Paraneoplastic pemphigus	IgG keratinocyte cell surface; C3, granular/linear at epidermal basement membrane (normal stratified and nonstratified squamous epithelium)	IgG binds keratinocyte cell surface	Plakin proteins, DSG1, DSG3
Bullous pemphigoid	Linear IgG, C3 at epidermal basement membrane	IgG binds in linear pattern normal stratified squamous epithelium basement membrane (epithelial side)	180-kDa, BPAg2 230-kDa, BPAg1
Herpes gestationis	Linear C3 at epidermal basement membrane (in 30–50% of patients linear IgG also seen)	IgG binds in linear pattern normal stratified squamous epithelium basement membrane (epithelial side)	180-kDa, BPAg2
Linear IgA bullous dermatosis	Linear IgA at epidermal basement membrane	IgA binds in linear pattern normal stratified squamous epithelium basement membrane (epithelial side)	97-kDa protein (portion of BPAg2)
Epidermolysis bullosa acquisita	Linear IgG epidermal basement membrane (IgA rarely)	IgG binds in linear pattern normal stratified squamous epithelium basement membrane (dermal side)	Type VII collagen (noncollagenous domain)
Dermatitis herpetiformis	Granular IgA dermal papillary tips	Negative	Epidermal transglutaminase (TGase 3)

IF, immunofluorescence; Ig, immunoglobulin.

slowly tapered toward alternate-day therapy. Although many patients are controlled on this regime, disease activity may flare during the corticosteroid taper. These patients require individualized management and often need additional immunosuppression.

When additional immunosuppressive agents are required, azathioprine, cyclophosphamide, mycophenolate mofetil, methotrexate, or ‘Cyclosporine’ are most often utilized. However, no prospective controlled trials have demonstrated the superiority of these agents in the treatment of PV compared to corticosteroids alone. The relatively low toxicity of azathioprine (1–3 mg/kg per day) make this drug the first choice as an additional immunosuppressive agent. Other agents, including parenteral gold compounds, plasmapheresis, and extracorporeal photochemotherapy, have also been suggested as adjunctive therapy. Treatment for patients with PF follows many of the principles established for treating PV; however, PF is in general less severe and rarely fatal, and therapy should be designed with this in mind. Dapsone has proved to be the mainstay of therapy for patients with intraepidermal IgA neutrophilic dermatosis, probably owing to its effect on the cutaneous neutrophilic infiltrate.⁶ Occasionally systemic glucocorticoid therapy may be needed,

either alone or in conjunction with dapsone. Therapy for paraneoplastic pemphigus has been disappointing and in general unsuccessful.

Recently biological agents such as rituximab, infliximab, etanercept, and high-dose intravenous immunoglobulin have been utilized for the treatment of patients with pemphigus with some success, but no controlled studies have been performed to date.

BULLOUS PEMPHIGOID

CLINICAL FEATURES

Bullous pemphigoid (BP) is characterized clinically by extremely pruritic, tense blisters that can occur on either inflamed or noninflamed skin (Fig. 63.3). These can range in size from small (1–5 mm) vesicles to large bullous lesions several centimeters in diameter. In addition to the characteristic tense blisters, patients with BP can also present with a variety of other skin manifestations, including urticarial lesions, vesicular lesions or, rarely, eczematous dermatitis. Blisters can occur on any part of the skin, but are often found on the extremities, groin, and axilla. Oral and ocular

Fig. 63.3 Patient with bullous pemphigoid showing erythematous plaques with tense subepidermal blisters.

Fig. 63.4 Direct immunofluorescence of perilesional normal-appearing skin from a patient with bullous pemphigoid using antibodies directed against human C3. A linear band of C3 is present at the basement membrane.

KEY CONCEPTS

BULLOUS PEMPHIGOID

- >> Tense subepidermal blisters
- >> Oral mucous membrane lesions are rare
- >> Subepidermal blister, most often with inflammatory infiltrate with eosinophils
- >> Linear deposits of immunoglobulin G and C3 at the dermal–epidermal junction (antigenic target 230 and 180-kDa hemidesmosomal proteins)

mucosal lesions occur infrequently in patients with BP, in contrast to patients with cicatricial pemphigoid (CP), who have predominantly mucosal lesions.

Although BP is primarily a disease of the elderly, with most patients being over 60, BP can develop at any age. BP has also been reported in association with other diseases, including diabetes mellitus, psoriasis, other autoimmune diseases, and malignancy. The association with malignancy has been noted in case reports and retrospective studies for many years. However, when age- and sex-matched control studies were performed, no statistically increased incidence of malignancy was documented in patients with BP.²⁰ BP has also been associated with drugs, with furosemide and phenacetin being the most commonly noted. Finally, environmental factors such as ultraviolet light and therapeutic radiation have been reported to precipitate BP. In general, the prognosis for patients with BP is good, with a 1-year survival in the USA reported to be approximately 90%. European studies, however, have reported a significantly higher mortality rate; the reasons behind this difference are not currently understood.

Biopsy of an early lesion of BP can reveal a number of different patterns, consistent with the polymorphic appearance of the eruption. The classic finding is a subepidermal blister with an inflammatory infiltrate in the dermis, comprised predominantly of eosinophils with an admixture of lymphocytes, histiocytes, and neutrophils. The epidermis over this blister is often intact with minimal abnormality, while the blister cavity is filled with inflammatory cells. Variants of this presentation can be seen, including a neutrophil-predominant inflammatory infiltrate, and a cell-poor variant with few inflammatory cells. Occasionally, an early lesion of

BP may not show a subepidermal blister but just edema of the epidermis, with an infiltrate of eosinophils. Because of the polymorphic histology of BP, it is important to realize that the diagnosis is not solely dependent on the histologic and clinical findings.

Patients with BP usually have IgG and/or C3 deposits present in a linear pattern at the dermal–epidermal junction (DEJ) and many have circulating IgG antibodies that bind in a similar linear pattern at the DEJ of normal human skin. Direct immunofluorescence studies of perilesional skin are key to the diagnosis of BP. Some 90–100% of patients with BP have linear deposits of C3 at the DEJ, whereas 70–90% of patients have linear deposits of IgG at the DEJ (Fig. 63.4). C3 may be the only immunoreactant seen in the skin of some patients with BP. By indirect immunofluorescence analysis, 70–90% of patients with BP have circulating IgG that binds in a linear pattern at the DEJ of normal human skin. Although these antibodies are often present at high levels, no consistent relationship has been demonstrated between the presence or level of antibodies directed against the DEJ and clinical disease activity or prognosis.

Although the immunofluorescent findings in patients with BP are characteristic, they are not diagnostic. Other immunologically mediated blistering diseases, such as the bullous eruption of systemic lupus erythematosus, herpes gestationis (HG), and epidermolysis bullosa acquisita (EBA), can have similar patterns of immunoreactivity. Gammon and co-workers reported that the use of normal human skin split with 1 mol/L NaCl can help in distinguishing antibodies directed against BP antigen(s) and the EBA antigen.²¹ NaCl treatment splits the skin within the lamina lucida, and IgG from patients with BP binds to the epidermal side only or to the epidermal and dermal sides, whereas antibodies from patients with EBA bind only to the dermal side (Fig. 63.5). Similar studies with NaCl-treated skin of BP patients demonstrated that IgG deposited *in vivo* is also localized to the epidermal side of the split skin.

PATHOGENESIS

Immunoelectron microscopic studies have demonstrated that the *in vivo* deposits of IgG are localized to the lamina lucida of the basement membrane. The target antigens are components of hemidesmosomes, which are the major attachment site of epidermal basal cells and serve as the site of linkage for cytoskeletal proteins through the plasma membrane to the dermis. Characterization of the antigen–antibody interaction in patients with BP has revealed two predominant antigens that are 230-kDa and 180-kDa proteins.

Fig. 63.5 Indirect immunofluorescence using serum from a patient with bullous pemphigoid. Serum was incubated with frozen sections of normal human skin which had been incubated with 1 mol/L NaCl. Immunoglobulin G deposits are present on the epithelial basement membrane associated with the epidermis and not on the dermal side of the split skin.

The 230-kDa and 180-kDa BP antigens have both been cloned and sequenced, confirming that they are distinct proteins, associated as a complex within the hemidesmosome in the native state. The 230-kDa BP antigen (BPAG1) is an intracellular protein with sequence homology to the desmosomal protein, desmoplakin I, a member of an adhesion junction plaque protein family. The 180-kDa BP antigen (BPAG2) contains both intra- and extracellular domains joined by a transmembrane region. The extracellular portion of this protein is remarkable for the presence of alternating collagen and noncollagen domains and has also been termed type XVII collagen. Epitope mapping studies of the 180-kDa protein have identified an immunodominant epitope that maps to an extracellular domain adjacent to the transmembrane region that is also a target for IgG antibodies in the sera of patients with herpes (pemphigoid) gestationis.²²

Although patients with BP have antibody reactivity against both BPAG1 and BPAG2, the role of these autoantibodies in the pathogenesis of BP has not been clearly established. The 230-kDa BPAG1 is located inside the cell, and it is unclear how the autoantibodies may have access to the antigen. Target disruption of the gene encoding BPAG1 did not result in blister formation or epidermal–dermal adhesion abnormalities. These results suggest that antibodies to BPAG1 may not directly inhibit the function of BPAG1. They may, however, play an important role in maintaining or enhancing the inflammatory response in patients with BP.

Patients with BP and with herpes (pemphigoid) gestationis develop antibodies against a specific noncollagenous, extracellular portion of the BPAG2 molecule.²² Serum levels of autoantibodies directed against BPAG2 have also been correlated with disease activity in patients with BP.²³ Further evidence for the important role for BPAG2 in BP is provided by the observation that patients with a form of inherited skin blistering and generalized atrophic benign epidermolysis bullosa have a mutation in BPAG2 that results in a dysfunctional or missing protein.²⁴

In order to develop an animal model of BP, rabbits were immunized to produce antibodies directed against the region of the mouse BPAG2, which corresponds to the immunodominant region of the human BPAG2. Passive transfer of this rabbit IgG to newborn mice resulted in the development of clinical blisters, an inflammatory infiltrate, and the deposition of immunoreactants. In this model complement activation, mast cell degranulation, and neutrophil infiltration are important in blister formation.²⁵

Complement activation and other extracellular mediators also appear to be involved in the pathogenesis of the skin lesions of BP. Complement

and the terminal components of the complement cascade are present in the skin of patients with BP. Early lesions in BP patients contain eosinophil granule proteins, suggesting that eosinophils play an important role in the early development of the lesions. A 92-kDa gelatinase produced by eosinophils present in the skin of patients with BP is capable of cleaving BPAG2.²⁶ Together, these findings support the hypothesis that the IgG autoantibody binds to the BP antigen, initially most likely BPAG2, and activates the complement cascade and the local production of cytokines, resulting in an accumulation of eosinophils and neutrophils that release enzymes, including gelatinases, leading to blister formation. Recent findings have also demonstrated IgE antibodies directed against BPAG2 in the serum of patients with BP, suggesting that IgE antibodies may play an important role in the early lesions of BP and the development of the eosinophil-dominant inflammatory infiltrate.²⁷

The factors that induce the development of autoantibodies in patients with BP are unknown. T cells from patients with BP respond *in vitro* to the extracellular region of the BPAG2,²⁸ and this reactivity is restricted by HLA-DQB1*0301. Normal HLA-DQB1*0301 subjects showed similar T-cell reactivity, but whereas T cells from the patients with BP produced both Th1- and Th2-type cytokines, normal subjects only produced Th1-type cytokines. These results suggest that the ability to mount a Th2 T-cell response to the BP antigen(s) may play a critical role in the development of the disease.

THERAPY

The mainstay of therapy for patients with BP is systemic glucocorticoids. The majority respond rapidly to 0.5–2.0 mg/kg per day of oral prednisone. Mild or localized disease can sometimes be managed by the use of potent topical corticosteroids; however, this form of BP often progresses to more severe involvement, necessitating systemic therapy. When new blister formation has stopped and healing has begun, a slow taper of the systemic steroids can be commenced. The speed of the taper is often dictated by the severity of the patient's initial disease and the minor flares that may occur during the taper. The majority of patients can be tapered off systemic steroids completely within 6–18 months. Recurrence of active disease is not uncommon. These episodes should be managed with the minimal amount of systemic steroids possible and can occasionally be treated just using topical corticosteroid therapy. In general, BP is a self-limiting process, which usually lasts between 1.5 and 5 years, and responds promptly to treatment with systemic glucocorticoids.

A minority of patients require prolonged high-dose systemic glucocorticoids. In these individuals the addition of immunosuppressive agents such as azathioprine, cyclophosphamide, or methotrexate will often allow tapering or discontinuation of systemic steroid therapy. Few prospective, controlled studies have been done to determine which of these drugs, if any, is superior as a steroid-sparing agent. One controlled study failed to demonstrate any substantial benefit from using either plasmapheresis or azathioprine in addition to systemic glucocorticoids in BP.²⁹ It is important to note, however, that this study did not address the utility of these agents in patients who had initially been unable to discontinue therapy with systemic glucocorticoids. Other unproven adjunctive therapies that may help in some patients include mycophenolate mofetil, dapsone, cyclosporine and tetracycline with niacinamide. When additional therapy is needed, we favor the use of azathioprine at doses of 1–2 mg/kg per day. A recent analysis of controlled trials published for the treatment of patients with BP concluded

KEY CONCEPTS

EPIDERMOLYSIS BULLOSA ACQUISITA (EBA)

- >> Classic EBA with subepidermal blisters, extreme fragility of acral skin
- >> Inflammatory EBA with subepidermal blisters similar to bullous pemphigoid
- >> Oral, conjunctival, and other mucous membrane lesions frequent
- >> Linear deposits of immunoglobulin G at the dermal-epidermal junction, localized to the dermis (antigenic target = type VII collagen)

that very potent topical steroids may be effective and safe and that starting doses of prednisolone above 0.75 mg/kg per day do not offer any greater benefit.³⁰

EPIDERMOLYSIS BULLOSA ACQUISITA

EBA is a chronic subepidermal blistering disease that typically presents in the fourth to sixth decades. Patients with the classic form of EBA present with peripherally distributed blisters that heal with scarring and milia formation. The skin of these patients is extremely fragile, often resulting in numerous erosions in areas of mechanical trauma, such as the hands, feet, elbows, and knees. Oral mucous membrane lesions, including esophageal involvement, are often seen. In addition, patients with classic EBA may develop lesions in the ocular, vaginal, urethral, and rectal mucosae. Ocular changes are common and these patients may clinically resemble those with CP. Other cutaneous manifestations include scarring alopecia and variable degrees of nail dystrophy. Patients can also present with a nonclassic or inflammatory type of EBA, the clinical presentation of which is essentially identical to that seen in BP, with widespread tense blisters on an erythematous base, which heal without scarring.

EBA has been associated with a variety of other diseases, particularly inflammatory bowel disease and systemic lupus erythematosus. Part of the explanation for these associations may be the result of the association of EBA with the specific HLA type, DR-2.

Skin biopsies of early lesions from patients with EBA reveal subepidermal blisters with variable degrees of inflammatory response. In patients with classic EBA lesional skin biopsies often have a minimal inflammatory cell infiltrate. In contrast, patients with the inflammatory variant may have substantial collections of inflammatory cells in the superficial dermis, usually consisting of an admixture of mononuclear cells, PMN, and eosinophils.

Direct immunofluorescence shows deposition of immunoreactants, most often IgG, at the DEJ in patients with EBA. Direct immunofluorescence of perilesional skin biopsies from patients with EBA displays a pattern of immunoreactants similar to that seen in patients with BP, with linear deposits of IgG at the DEJ. Linear deposits of C3, IgM, IgA, and

fibrinogen have also been reported in patients with EBA. However, the immunoreactants in the skin of patients with EBA have a different localization from those in the skin of patients with BP. In EBA, the immunoreactants are localized exclusively below the lamina lucida. This distinctive localization of immunoreactants can be visualized by incubating the patient's skin biopsy with 1 mol/L NaCl, which splits the skin at the basement membrane zone. Direct immunofluorescence testing of this "split skin" from patients with EBA will localize the *in vivo*-deposited IgG to the floor of the *in vitro*-generated blister, whereas in patients with BP, the IgG localizes to the blister roof.

Indirect immunofluorescence using stratified squamous epithelia such as normal human skin shows circulating anti-basement membrane-zone antibodies in 30–50% of patients with EBA. When NaCl-treated split skin is used as a substrate, however, IgG antibody can be detected in up to 85% of patients, making this a more sensitive and specific substrate for clinical testing. As would be expected based on the *in vivo* deposition pattern, IgG from patients with EBA localizes to the blister floor. With the improved immunologic characterization of patients with EBA it has become apparent that patients with various other clinical presentations also have antibodies in sera and skin identical to those seen in EBA. One such group includes patients with the bullous eruption of systemic lupus erythematosus, who have a vesiculobullous eruption that is clinically and histologically similar to dermatitis herpetiformis (DH). However, many of these patients have a linear band of IgG at the DEJ that localizes to the floor of 1 mol/L NaCl split skin. Another clinical presentation with EBA-like antibodies against the DEJ of skin is CP. These patients have a limited blistering eruption of the skin with marked mucosal involvement, including oral and ocular inflammation and scarring. These phenotypes are now included in the spectrum of EBA on the basis of the immunologic studies described above, as well as the discovery that antibodies against type VII collagen are demonstrable in each of them.

PATHOGENESIS

Immunoelectron microscopy has shown immunoglobulin deposits in patients with EBA localized to the lamina densa zone of the basement membrane, below the lamina lucida. Standard transmission electron microscopy of lesional skin of patients with EBA shows that the anchoring fibrils are decreased or absent. These findings may be relevant in the development of the clinically evident skin fragility, as anchoring fibrils are postulated to play a role in epidermal-dermal adherence via the linkage of the hemidesmosome through the basement membrane. The lack of an inflammatory infiltrate in many patients with EBA suggests that these autoantibodies may disrupt the interaction between anchoring fibrils and dermal matrix proteins.

The target antigen for the IgG autoantibodies present in the sera of patients with EBA is type VII collagen, a 300-kDa glycoprotein composed of a 145-kDa noncollagenous domain (NC1) at the amino-terminal end, an 18-kDa noncollagenous domain (NC2) at the carboxy-terminus, and a central collagenous domain. IgG antibodies from patients with EBA appear to be specific for epitopes within the NC1 noncollagenous domain of the protein. Type VII collagen is the major structural component of anchoring fibrils and is produced by both epithelial keratinocytes and dermal fibroblasts. Recently, passive transfer experiments using mice, as well as active immune models, have provided additional support for the critical role of antibodies directed against type VII collagen in the pathogenesis of EBA.³¹

TREATMENT

Spontaneous resolution is infrequent in EBA, and management is difficult. The main goals of therapy are to minimize blistering and scar formation, with particular concern for ocular and oral mucosal lesions. Systemic glucocorticoids are the mainstay of therapy, especially for patients with the inflammatory variant of EBA. Unfortunately, even high-dose systemic steroids do not usually affect fragility and trauma-induced blister formation of the skin. Mucosal lesions often respond to systemic steroids in doses of 0.5–1.5 mg/kg per day, but recur with tapering and/or discontinuation of steroids. Several agents have been proposed as adjunctive agents, including azathioprine, cyclophosphamide, dapsone, hydroxychloroquine, and plasmapheresis. However, none has been consistently demonstrated to be effective. Cyclosporine has been used to treat patients with EBA with some success, although toxicity has limited therapy in some cases. Photophoresis and intravenous immunoglobulin have also been reported to be effective in some patients with refractory EBA.³² Rituximab has also been used successfully in EBA in a single case report.³³

Mucous membrane lesions can prove particularly difficult to manage and may necessitate systemic therapy. Ocular lesions should be followed by an ophthalmologist and may require systemic glucocorticoids to prevent conjunctival scarring. Oral mucous membrane lesions can sometimes be managed with frequent application of potent topical steroid ointments or gels (0.05% clobetasol propionate, 0.05% fluocinonide). If this fails and the degree of oral erosions is inhibiting the maintenance of appropriate nutrition, systemic glucocorticoid therapy may be required. In addition, clinicians should always be aware of possible involvement of the esophageal and/or tracheal mucosa and involve appropriate specialists to monitor and treat these potentially severe complications.

The management of chronic skin wounds is of primary importance in the care of EBA patients. Protection of the skin from trauma and the early use of topical and systemic antibiotics when infections develop are critical to improving the rate of healing. The recent development of new biological dressings for chronic ulcers has also proved helpful in the management of these wounds.

HERPES (PEMPHIGOID) GESTATIONIS

HG is a rare, itchy blistering disease of pregnancy and the puerperium characterized by linear deposits of IgG and C3 at the DEJ.³⁴ The descriptor of ‘herpes’ was initially chosen because of the frequent appearance of groups of vesicular lesions, similar to those seen in primary herpetic infections of the skin. However, HG has no relationship to herpes virus infections. Recently some workers have proposed renaming this eruption pemphigoid gestationis, emphasizing its close association with BP.

HG is rare, occurring in fewer than 1 per 50 000 pregnancies in North America. It usually presents in the third trimester or in the immediate postpartum period. Although it may recur in subsequent pregnancies, this is not absolute. Disease flares in the immediate postpartum period do occur, and patients have been reported to develop blisters when menses return or when oral contraceptives are used.

HG presents as tense blisters, often on an urticarial base, ranging in size from small (3–5 mm) vesicles to large (1–2 cm) bullae. The blisters often begin on the abdomen, although the entire body can be involved. Pruritus is a common feature and can be quite severe.

HG is associated with maternal morbidity and increased fetal morbidity and mortality. The maternal morbidity is mainly related to the skin disease, with extensive itching and blister formation. Fetal morbidity and mortality were previously estimated to range as high as 30%, but several subsequent studies have suggested that this figure is too high.³⁵ Prematurity and low birth weight may be associated with HG. Infants born to mothers with HG may also develop skin lesions similar to those seen in the mother, due to transplacental passage of maternal autoantibodies. The skin lesions seen in these infants resolve spontaneously with the clearance of maternal immunoglobulin.

The histopathology of HG lesions is not diagnostic. Subepidermal blisters are seen with a perivascular infiltrate containing eosinophils, neutrophils, lymphocytes, and monocytes. Necrotic basal keratinocytes can also be seen. None of these findings is sufficiently distinct, however, to separate HG from other subepidermal blistering diseases on the basis of histologic appearance alone.

Direct immunofluorescence studies of the skin of patients with HG reveal a linear pattern of C3 at the DEJ. In addition, 30–50% of patients have linear deposits of IgG in a similar pattern. Occasionally other immunoreactants, including IgA, IgM, C1q, C4, properdin, factor B and C5, may be present, localized to the lamina lucida region of the DEJ. Indirect immunofluorescence reveals circulating IgG antibodies directed against the epidermal basement membrane in only ~30% of patients. If, however, a complement fixation technique is used, 50–75% of patients will have evidence of IgG antibody directed against epithelial basement membrane. This IgG anti-basement membrane antibody is detected by its ability to fix complement *in vitro*, but cannot be directly detected by routine indirect immunofluorescence due to its low concentration. This autoantibody can cross the placenta, and infants born to mothers with HG will often have C3 deposits at the DEJ, even in the absence of clinical skin disease. The use of 1 mol/L NaCl split skin as the substrate for indirect immunofluorescence has revealed that the IgG antibody present in the serum of patients with HG binds to the epithelial side of the split skin,³⁶ a pattern identical to that seen in BP.

PATHOGENESIS

Sera from most patients with HG bind to the 180-kDa BPAG2, but do not react with the 230-kDa BPAG1 antigen.³⁶ In addition, T cells from patients with HG react to peptides from BPAG2.³⁷ The critical role of pregnancy and other hormonal factors in the development of HG is not understood.

An increased frequency of the HLA-DR3 haplotype has been demonstrated in patients with HG, and the greatest relative risk is associated with the presence of both HLA-DR3 and -DR4. It has also been reported that patients with HG have an increased frequency of anti-HLA antibodies compared to multiparous control subjects. Although some data suggest that the paternal haplotype is important in the pathogenesis of HG, further prospective studies are indicated. Patients with HG are also reported to have an increased frequency of the C4 null allele, although this has been postulated to be secondary to the increased frequency of HLA-DR3 in this patient population.

TREATMENT

Therapy of patients with HG is directed at relieving the significant pruritus and preventing the development of new blisters. If the extent of disease is limited, patients can be managed with topical glucocorticoids and antihistamines.³⁴ Most patients, however, have more significant disease and require the use of systemic glucocorticoids. Treatment with prednisone 20–60 mg/day is sufficient to control both the pruritus and new blister formation in the vast majority of cases. Every attempt should be made to reduce the corticosteroids to the lowest possible effective dose. Occasionally it may be possible to stop prednisone before delivery. However, the physician should be aware that flares of HG are often seen in the immediate postpartum period. Only rarely will patients require therapy beyond the initial postpartum period. In patients who require prolonged therapy postpartum, immunosuppressive agents such as those used in the other blistering diseases should be considered. Patients being treated with either systemic steroids or immunosuppressive drugs should be counseled with regard to breast-feeding restrictions.

Occasionally infants born to mothers with HG will have skin lesions.³⁴ These are limited in extent and resolve spontaneously with the disappearance of maternal IgG from the infant's circulation.

■ CICATRICAL PEMPHIGOID ■

CP is a rare, chronic, scarring blistering disease that predominantly affects the oral and conjunctival mucosae. Involvement of the conjunctiva can range from a mild conjunctivitis to severe conjunctival inflammation leading to symblepharon formation, entropion, trichiasis, corneal scarring and, eventually, blindness in some patients. Oral mucosal lesions include gingivitis, often with erosions and desquamation, as well as erosions and ulcerations on the buccal mucosa and the hard and soft palates. Rarely esophageal and laryngeal involvement is seen with resultant scarring and stenosis. Other mucosal sites that can be involved include the genitalia, rectum, and nasopharynx. Cutaneous involvement occurs in 10–25% of patients, although it is often limited in extent and located predominantly on the scalp, back, or face.³⁸

Mucosal biopsies reveal a subepidermal blister with a cellular infiltrate that is usually composed of lymphocytes and plasma cells. Increased numbers of neutrophils or eosinophils have also been reported. Skin biopsies of lesions in patients with CP are essentially indistinguishable from those seen in BP.

Direct immunofluorescence of perilesional skin or mucosal samples reveals a linear deposit of immunoreactants at the basement membrane zone.³⁹ The majority of patients with CP have IgG and C3 deposits at the basement membrane, although the presence of other immunoreactants, including IgA, IgM, and fibrin, has also been reported. It is important to note that, in patients with ocular or oral mucosal CP who do not have skin lesions, an undirected skin biopsy for immunofluorescence is of little diagnostic use. Similarly, biopsy of the conjunctiva can sometimes yield negative immunofluorescence results in patients with otherwise typical CP. This may be due to the inflammation present in the conjunctiva. In such patients a careful evaluation for mucosal lesions and biopsy of the perilesional mucosa is often diagnostic. On immunoelectron microscopy, immunoreactants have been localized within both the lamina lucida and the lamina densa.

Circulating anti-basement membrane-zone antibodies may be present in low titer, but are usually absent in patients with CP. Attempts to improve

the yield of indirect immunofluorescence by using a variety of tissue substrates, including oral and conjunctival mucosa, normal human skin, and normal human split skin, have for the most part been unsuccessful.

PATHOGENESIS

Our understanding of the pathogenesis of CP has been hampered by both the heterogeneous clinical presentation and the lack of high-titer serum antibodies. The identification of different immunoglobulin classes at the basement membrane using immunofluorescence and the different localization of those immunoglobulins in the basement membrane on immunoelectron microscopy support the hypothesis that CP is a heterogeneous disease, with a variety of basement membrane-zone proteins serving as relevant targets. Chan and co-workers have correlated the clinical presentation, immunopathology, and target antigens in a group of patients with immune-mediated subepithelial blistering disorders of the mucous membranes.³⁹ About 90% of patients with both skin and mucous membrane lesions or mucous membrane lesions alone had immunoreactants present on direct immunofluorescence. In contrast, only 40% of patients with isolated ocular disease had C3 and/or IgG deposits. This finding may reflect the difficulty encountered in biopsies of the inflamed conjunctiva. Of more interest, however, were the results of indirect immunofluorescence: 11 of 14 (81%) patients with skin and mucous membrane disease had circulating IgG anti-basement membrane-zone antibodies, of which 9 identified BPAG1 and BPAG2 by immunoblot and/or immunoprecipitation. In contrast, only 3 of 24 patients with only oral mucosal lesions or ocular lesions had positive indirect immunofluorescence, one of which reacted with the BP antigens.

Other investigators have reported antibody reactivity in patients with CP to a variety of epidermal and dermal proteins. Sera from patients with CP have been shown to react with BPAG2. Sera from ocular CP patients have been reported to react with a 205-kDa protein that has homology with the cytoplasmic domain of β_4 -integrin and a 45-kDa protein. Some patients with a clinical phenotype suggestive of CP have autoantibodies directed against epiligrin, a ligand for major keratinocyte integrins ($\alpha_3\beta_1$ and $\alpha_6\beta_4$). Characterization of patients with anti-epiligrin CP is of importance due to the increased risk of malignancy in these individuals.⁴⁰ These data suggest that the clinical presentation of CP is associated with a heterogeneous group of autoantibodies that react with multiple antigens of the skin basement membrane zone. The different clinical presentations may therefore result from not only different target antigens, but also perhaps different antibody-binding sites on antigens such as the BP antigen.

The HLA antigen DQB1*0301 has been found to occur with an increased frequency in Caucasian patients with isolated ocular, or with ocular and oral mucosal CP.^{41,42} Chan and co-workers reported that this association was not found in patients with oral mucosal disease without ocular disease, and suggested that the increased frequency of the DQB1*0301 allele may play a role in the development of ocular disease.⁴² These results need to be confirmed in larger populations.

THERAPY

Treatment of CP is difficult and directed at minimizing the scarring and resultant complications that can occur in the eye. Dapsone in doses of 100–200 mg/day has been found by many investigators to be effective at controlling the early inflammatory response in patients with CP.⁴³ Some

investigators have also found that tetracyclines, often in combination with nicotinamide, can control the inflammatory process seen in patients with CP. If this therapy is unsuccessful, treatment with systemic glucocorticoids (1–2 mg/kg per day), often with adjunctive immunosuppressive therapy such as azathioprine or cyclophosphamide, may be needed. Intravenous immunoglobulin has been reported to be useful by some authors, but no controlled studies have been performed. Isolated case reports also suggest that therapy with mycophenolate mofetil or plasmapheresis may be of benefit in some patients with CP, but again no control studies or large series using these therapies have been reported. It is important to note that the clinical course of CP is difficult to predict and that the response to treatment in some patients is often suboptimal. Some patients are able to achieve long-lasting remissions, but active disease frequently recurs and patients in remission should be followed closely.

Ocular mucosal lesions may often be severe and can represent significant morbidity in patients with CP. Consultation with an ophthalmologist is important in managing the potentially severe ocular complications seen in patients with CP. Physicians should also be aware of the potential for esophageal and tracheal disease activity and consultation with physicians with expertise in gastroenterology and otolaryngology is often required for patients with severe disease. Oral mucosal lesions can often be managed with potent topical corticosteroids (0.05% clobetasol propionate ointment, 0.05% fluocinonide gel) applied frequently to lesions. In severe cases dapsone or systemic glucocorticoids may be needed. Patients with limited amounts of skin disease can often be managed with topical therapy alone. If this fails, management techniques such as those discussed for patients with BP are usually successful.

■ LINEAR IgA BULLOUS DISEASES ■

Linear IgA bullous disease (LABD) is a clinically heterogeneous blistering disease in which direct immunofluorescence of perilesional skin biopsies reveals the presence of a linear band of IgA at the basement membrane zone.⁴⁴ The majority of patients with LABD present with pruritic vesicles and papules, localized primarily to the extensor surfaces, similar to the clinical pattern seen in patients with DH. Patients with LABD do not, however, have an associated gluten-sensitive enteropathy, are not able to control their disease by a gluten-free diet, and do not have the characteristic HLA associations of patients with DH.

Other patients with linear IgA deposits may present with a clinical picture more suggestive of BP, with pruritic tense blisters on an erythematous base. Other clinical presentations have been described with clinical as well as histologic and immunopathologic overlap between patients with LABD and CP or EBA. Finally, children can develop a subepidermal blistering disease with linear IgA deposits; this was previously termed chronic bullous disease of childhood.⁴⁴ In these cases the blisters occur mainly in flexural areas, with pruritus that is more variable in degree than in many other blistering diseases.

Routine histopathology of lesional skin of patients with LABD reflects the clinical heterogeneity seen in these patients. Biopsy usually reveals collections of neutrophils in the dermal papillary tips in a pattern virtually identical to that seen in biopsies from patients with dermatitis herpetiformis (DH). However, subepidermal blisters with eosinophils, as observed in patients with BP, may also be seen.

Direct immunofluorescence of perilesional skin in patients with LABD reveals a linear band of IgA at the basement membrane zone,

which has been characterized to be almost exclusively IgA₁.⁴⁴ Further characterization of these IgA deposits in the skin has revealed that both κ and λ light chains are present, indicating that the antibodies are polyclonal. In addition, J chain has not been detected, suggesting that the IgA is monomeric and may not be of gut origin. Immunoelectron microscopic localization of the immunoreactants has most often revealed IgA deposits in the lamina lucida; however, sublamina densa IgA deposits have also been noted. Circulating IgA antibodies against the basement membrane zone of stratified squamous epithelium have been detected in only 10–30% of patients (children and adults) with linear IgA deposits. Other immunoreactants, especially IgG and C3, have been found in 30–40% of these patients.

PATHOGENESIS

The absence of circulating antibody has made it difficult to determine the antigenic target in LABD. Zone et al. reported that sera from both adults and children with linear IgA deposits within the lamina lucida reacted with a 97-kDa protein that is identical to a portion of the 180-kDa BP antigen BPAG2.⁴⁵ In patients with LABD or linear IgA disease of childhood and who have sublamina densa IgA deposits, investigators have identified reactivity to type VII collagen, and to an unknown 285-kDa dermal protein.⁴⁶ These findings support the hypothesis that the target antigens in LABD, including linear IgA disease of childhood, are heterogeneous. Regardless of the location of the IgA deposits or the specific antigenic target, the mechanism of lesion formation in patients with LABD remains unknown.

THERAPY

Dapsone is the mainstay of therapy of patients with all forms of LABD. The exact mechanism of its action is not known, but, as discussed above, this drug seems most useful in diseases with marked neutrophil infiltrates in lesional skin. The dosage needed to control the cutaneous eruption ranges from 25 to 200 mg/day. Most patients can be controlled with 100 mg/day, with minimal side effects. Although dapsone is well tolerated by most patients, it does have significant pharmacologic and idiosyncratic adverse effects and should only be used by physicians experienced in its use. Occasionally patients may not respond to dapsone alone. In these cases the addition of low doses of systemic glucocorticoids (prednisone 10–20 mg/day) may result in significant improvement. If patients cannot tolerate dapsone, systemic glucocorticoids in doses of 40–60 mg/day are usually effective. However, as most adult patients with LABD require long-term therapy, treatment with prednisone should be avoided whenever possible.

■ DERMATITIS HERPETIFORMIS ■

CLINICAL FEATURES

DH is an intensely pruritic blistering disease that classically presents in the second or third decade with erythematous papules and/or vesicles localized over the extensor surfaces (Fig. 63.6). Patients often present with a broad spectrum of lesions. The severe pruritus leads to patients scratching the small papules and vesicles and as a result they often present with multiple erosions. Patients can also present with urticarial

Fig. 63.6 Patient with dermatitis herpetiformis showing erythematous papules with crusts on the elbows. Rare intact vesicles are present.

plaques or, more rarely, frank bullae. Lesions are most often symmetrically distributed over the extensor surfaces, especially the elbows, knees, buttocks, back, and posterior hairline. Symptomatic mucous membrane lesions are rarely present. One clinical hallmark of DH is the extreme pruritus that patients experience. They characteristically report feeling a severe burning or stinging 12–24 hours before the appearance of a lesion, which persists until the vesicle is broken and the crust forms. Although the clinical manifestations of DH may wax and wane, DH is generally a lifelong dermatosis. The wide variety of clinical presentations of DH often suggests a long differential diagnosis, including erythema multiforme, HG, BP, transient acantholytic dermatitis, papular urticaria, scabies, bug bites, and neurotic excoriations.

The frequency of DH varies in different ethnic groups. In Anglo-Saxon and Scandinavian populations it has been estimated to be between 10 and 39 per 100 000 persons, whereas DH occurs much less frequently in other populations, such as African-Americans and Asians. This relates in part to the different frequency of the DH-associated HLA antigens in different populations.

Biopsy of an early lesion of DH reveals a characteristic neutrophilic infiltrate in the dermal papillae with the presence of fibrin, neutrophilic fragments, edema, and variable numbers of eosinophils. This histologic pattern is not specific; it has been reported in patients with BP, linear IgA disease, the bullous eruption of systemic lupus erythematosus, and leukocytoclastic vasculitis. When older bullous lesions are biopsied in patients with DH, the histologic features are often indistinguishable from those seen with other blistering disorders.

IgA is present at the DEJ of the skin of patients with DH (Fig. 63.7). Two patterns of IgA deposition were initially described in patients with identical clinical findings: 85–90% of patients had granular deposits of IgA at the DEJ, and 10–15% had a linear band of IgA at the DEJ. These patterns, consistent within a given individual, have now been shown to distinguish between two different diseases. Patients with linear IgA deposits have LABD (see previous section), whereas patients with

KEY CONCEPTS

DERMATITIS HERPETIFORMIS

- >> Extremely itchy, small blisters on extensor surfaces
- >> Associated with asymptomatic/gluten-sensitive enteropathy
- >> Increased frequency of human leukocyte antigen (HLA)-B8, -DR3, -DQ2 haplotype
- >> Granular deposits of immunoglobulin A at the dermal–epidermal junction (antigenic target unknown)
- >> Skin disease controlled by gluten-free diet

Fig. 63.7 Direct immunofluorescence of normal-appearing perilesional skin of a patient with dermatitis herpetiformis using antibodies against human immunoglobulin A (IgA). Granular deposits of IgA are present at the dermal–epidermal junction.

granular deposits of IgA are considered to have true DH. The granular deposits of IgA at the DEJ are specific for patients with DH and have not been found in those with isolated gluten-sensitive enteropathy (GSE) or asymptomatic relatives of patients with DH.⁴⁷

Granular deposits of IgA are found in both involved and uninvolved skin of patients with DH, including the oral mucosa. Consistent regional variations in the amount of IgA in the skin of patients with DH have not been reported. However, Zone and co-workers reported that IgA was either markedly decreased or absent in skin in which the patient reported never having had any lesions.⁴⁸ These observations suggest that biopsies taken for direct immunofluorescence studies should be obtained from normal-appearing perilesional skin in order to maximize the diagnostic yield.

IgG, IgM, and IgE are not usually found in the skin of patients with DH. The third component of complement, C3, along with early components of the alternative complement pathway, may be present in skin biopsies of patients with DH. The neoantigens of the C5–C9 membrane attack complex have also been reported to be present in normal-appearing skin of patients with DH. However, the co-localization of vitronectin with the C9 neoantigen suggests that the C5–C9 neoantigen is deposited

in DH skin as part of the nonlytic C5–C9 complex, and that the lytic membrane attack complex of complement may not play a primary role in the development of DH skin lesions.⁴⁹

Characterization of IgA in DH skin has shown that it contains both κ and λ light chains, indicating that the IgA is polyclonal. Secretory component, a transport protein bound to secretory IgA, has not been found in these IgA deposits. IgA₁ is the predominant subclass found in the skin of patients, with either minimal or no deposits of IgA₂ detected.⁵⁰ Although this would seem to suggest that the IgA in DH skin may not be mucosal in origin, IgA₁ is also the predominant subclass in the gastrointestinal secretions of patients with DH.⁵¹

In 1966 Marks and co-workers noted a gastrointestinal abnormality in 60–70% of patients with DH, which was histologically similar to that seen in isolated GSE.⁵² This abnormality was reversible with the avoidance of dietary gluten, confirming that DH was a gluten-sensitive disease. The histologic changes seen in the small bowel of patients with DH are characterized by flattening of the normal villous architecture of the jejunal epithelium, with elongation of the intestinal crypts and a mononuclear cell infiltrate both within the lamina propria and in an intraepithelial location. This disease is often patchy in character in both DH and isolated GSE, and in general the findings in patients with DH are less severe than those seen in isolated GSE. Essentially all patients with the clinical features of DH and granular IgA deposits have associated GSE.

Despite the morphological similarity of the intestinal abnormality seen in patients with DH and those with isolated GSE, most patients with DH have no gastrointestinal symptoms. Only 10% of patients with DH have the typical symptoms of isolated GSE, such as bloating, diarrhea, and malabsorption, whereas 20–30% may have mild steatorrhea. However, many patients with DH do have abnormal intestinal function, as documented by abnormal absorption of D-xylose, iron, folate, glucose, water, and bicarbonate.

Despite the asymptomatic nature of the GSE associated with DH, it is clear that it plays a critical role in the pathogenesis of DH. The observations that patients with DH who adhere to gluten-free diets can control their skin disease, normalize the morphologic changes of the small intestine, and after years of gluten avoidance lose the cutaneous IgA deposits, are strong evidence that the GSE plays a fundamental role in the pathogenesis of DH. However, the exact relationship between the skin disease, the cutaneous IgA deposits, and the associated GSE remains unknown.

Initial studies of HLA associations in patients with DH and granular deposits of IgA revealed that 70–90% of those with DH express the HLA class I antigen B8, compared to only 20–30% of control subjects. Subsequent studies showed that 90–95% of patients with DH express HLA-DR3, compared to about 23% of controls. In addition, 95–100% of DH patients express HLA-DQ2 (which is in linkage disequilibrium with HLA-B8 and -DR3), compared to 40% of controls. The HLA-DR and HLA-DQ alleles involved in the pathogenesis of DH are DQB1*0201, DQA1*0501, and DRB1*0301 and are essentially identical to those that have been described for patients with isolated GSE.

In addition to the striking association of DH with gluten-sensitive enteropathy, a number of other disease associations have been noted. For example, patients with DH have an increased frequency of gastric atrophy and gastric hypochlorhydria. Thyroid abnormalities, including hypothyroidism, hyperthyroidism, thyroid nodules, and thyroid cancer, also occur more frequently in patients with DH. A number of other autoimmune diseases, including systemic lupus erythematosus, dermatomyositis,

myasthenia gravis, Sjögren's syndrome, and rheumatoid arthritis, have also been reported in patients with DH. It is thought that many of these associations are related to the high frequency of the HLA-B8, -DR3, DQ-2 haplotype in patients with DH. Another important clinical association in patients with DH is an increased frequency of malignancy, specifically lymphomas. An increased standardized incidence ratio of 6.0 for non-Hodgkin's lymphoma has been reported, but no increased mortality was detected.⁵³

PATHOGENESIS

The pathogenesis of DH rests on three distinct associations: (1) granular deposits of IgA in the skin at the DEJ; (2) gluten-sensitive enteropathy (albeit most often asymptomatic); and (3) an increased frequency of the HLA-DR3/DQ2 haplotype. Attempts to understand DH must integrate all these factors.

The mechanism by which IgA binds to DH skin is not known. Circulating antibodies that bind to normal human skin *in vitro* have not been detected in patients with DH. The IgA deposits also do not appear to be the result of the presence of IgA-containing circulating immune complexes. These complexes have been found in 25–35% of patients with DH, but have also been detected in the serum of patients with isolated GSE, who do not have cutaneous IgA deposits.⁵⁴ Although these data suggest that circulating IgA immune complexes are not responsible for the IgA found in DH skin, it is possible that pathogenic immune complexes may have escaped detection by the available techniques.

A third mechanism by which IgA might bind to DH skin is that IgA produced in the gut, as a response to wheat or other dietary antigens, may reach the circulation where it could either bind to wheat protein deposited in skin or cross-react with normal structures or molecules in the skin. IgA antibodies against endomysium, a connective tissue element surrounding smooth muscle, have been found in the serum of patients with DH and have been determined to be directed against tissue transglutaminase.⁵⁵ Recent studies have demonstrated that patients with DH have IgA antibodies against epidermal transglutaminase with a higher avidity than found in patients with isolated GSE. In addition, the IgA deposits in DH skin have been found to co-localize with epidermal transglutaminase, suggesting that the IgA in the skin of DH patients is directed against epidermal transglutaminase.⁵⁶ However, the mechanism whereby the IgA deposits remains unknown.

In vitro studies have demonstrated that treatment of gliadin with tissue transglutaminase modifies gliadin peptides to allow recognition by T cells from the gut of patients with isolated GSE.⁵⁷ These observations suggest that modification of the wheat protein by tissue transglutaminase may play a role in the development of immunity to wheat seen in patients with isolated GSE and DH. The cytokine profile in the gut of patients with DH differs from that in patients with symptomatic isolated GSE: gut biopsies from patients with isolated GSE expressed significantly more interferon- γ than those with DH, while gut biopsies from DH patients expressed more IL-4.⁵⁸ It remains to be determined whether these findings relate to the lack of gut symptoms in patients with DH.

The presence of an ongoing mucosal immune response in patients with DH has been shown to result in systemic signs of inflammation, including elevated serum levels of soluble IL-2 receptor and IL-8, increased neutrophil expression of CD11b, and increased expression of endothelial cell E-selectin in the skin.⁵⁹ These findings suggest that the

mucosal immune response results in a proinflammatory environment in the skin that, when coupled with cutaneous IgA deposits, may result in the development of the typical skin lesions of DH.

THERAPY

DH can be treated either with dapsone or by adherence to a gluten-free diet, and the choice of therapy should be individualized to each patient. The treatment of choice for most patients with DH is dapsone or sulfapyridine, owing to the lack of gastrointestinal symptoms in most cases, as well as the difficulty of adhering to a strict gluten-free diet. Dapsone 100–200 mg/day is sufficient to control the cutaneous eruption in the majority of cases, with minimal side effects. Dapsone results in an almost immediate cessation of symptoms of the skin disease. It does not, however, affect the gastrointestinal mucosal defect or the gastrointestinal symptoms. Patients with DH on dapsone therefore have an ongoing (albeit low-grade) gluten-sensitive enteropathy. The exact mechanism of action of dapsone remains unknown. Dapsone appears to function at the level of the effector cells in the skin lesions, most likely the PMN, rather than affecting the mucosal immune response to wheat protein. Dapsone is a potentially toxic drug and patients should not increase the dose when disease flares occur without first consulting their physician.

The second mechanism of controlling the cutaneous eruption of DH is by strict adherence to a gluten-free diet. Nearly 80% of patients with DH who follow such a diet are able to stop or substantially reduce the dose of dapsone required to control their skin disease.⁶⁰ Patients may require at least 5 months on a gluten-free diet before being able to reduce their dose of dapsone, and 8–48 months of such a diet are necessary before they can discontinue their dapsone. Gluten-reduced diets, in which gluten content is not totally eliminated, appear to be less effective in controlling the cutaneous manifestations of DH, but may provide some relief. Patients on a gluten-reduced diet are able to decrease their dapsone dosage by approximately 50% compared to a 75% or greater reduction in patients on a gluten-free diet. Strict adherence to a gluten-free diet controls the cutaneous manifestations of DH in most patients, reverses the morphological changes in the small intestine, and after many years may result in disappearance of the cutaneous IgA deposits.⁶⁰ The cutaneous IgA has been found to return upon rechallenge with dietary gluten in these patients.⁶⁰

Rarely, patients with DH do not respond to a gluten-free diet despite what appears to be total dietary compliance. This has also been reported in patients with isolated GSE, and other dietary factors have been postulated to play a role. In support of this concept is the observation that the skin lesions and gastrointestinal changes of DH may also respond to an elemental diet, often within only 2–3 weeks of starting the diet. Of interest, these patients responded to an elemental diet even in the presence of dietary gluten. These results imply that other proteins besides gluten play a role in the pathogenesis of DH. Although a gluten-free diet is an attractive alternative to medication for many patients, it is difficult to maintain. Gluten is present in most common grains (wheat, rye, barley) but not in rice and maize. Recently it has been established that eating oats appears to be safe for patients with DH, but it is important to remember that oat products may be contaminated with wheat protein. The patient should be informed that the success or failure of the diet cannot generally be assessed until at least a year of therapy has been completed.

Myasthenia gravis

Arnold I. Levinson

64

INTRODUCTION

Myasthenia gravis (MG) is a disease characterized by weakness of striated muscles. The weakness is due to impaired neuromuscular transmission resulting from a reduction in the number of receptors for the neurotransmitter acetylcholine (ACh) at the postsynaptic myoneural junction. This reduction is caused by the action of anti-acetylcholine receptor (anti-AChR) antibodies. The disease occurs with a reported prevalence of 0.5–5/100 000 and an incidence of 0.4/100 000 per year. Although MG can occur at any age, it typically presents in the second and third decades of life, with a later peak occurring after age 50 (late-onset disease). A female preponderance (3:1–4:1) has been reported in the first 40 years of life; thereafter the incidence is comparable between the sexes.

CLASSIFICATION

MG patients have traditionally been divided into two categories: those with generalized disease and those presenting with disease limited to the ocular muscles.¹ Within these two groups, patients can be further subdivided on the basis of age of onset. Neonatal MG affects 10–20% of offspring born to myasthenic mothers. Disease manifestations are those of generalized MG (see below) but are transient, dissipating with the metabolism of maternal anti-AChR antibodies that had been transferred across the placenta during the third trimester of pregnancy. Several congenital myasthenic syndromes have been described. For the most part, these manifest during the neonatal period, persist into adulthood, and are not considered to have an autoimmune basis. Juvenile MG describes those patients who present with disease between 1 year of age and puberty. Apart from the age of onset, juvenile myasthenics behave like adult patients with MG.

Adults may present with ocular involvement or signs of more generalized disease. The ocular involvement is characterized by impaired ocular muscle motility and lid weakness, manifesting as diplopia and ptosis, respectively. The vast majority of MG patients will experience ocular involvement, with roughly 50% of patients presenting with ocular signs

at the time of diagnosis. Those generally at risk of disease progression are: (1) patients with evidence of subclinical disease on electrophysiological testing of limb muscles; and (2) patients who have markedly elevated titers of anti-AChR antibodies. Typically, patients with ocular symptoms for longer than 2 years will not progress to a more generalized form of disease.

In the generalized disease group patients can be classified into mild, moderate, and severe on the basis of clinical activity. Any skeletal muscle group may be affected, but typically the palatal, pharyngeal, and upper esophageal muscles are involved. This results in dysarthria, dysphagia, and difficulty in handling secretions. Involvement of the diaphragm and intercostal muscles produces dyspnea and may lead to respiratory failure. Involvement of the muscles of the extremities and trunk occurs in 20–30% of patients at initial presentation and causes difficulties with activities of daily living. The hallmark of all of muscle involvement in MG is its variability over time, with weakness usually exacerbated by repetitive use.

DIAGNOSIS

The differential diagnosis is extremely broad, encompassing neuropathies, primary and secondary myopathies, muscular dystrophy, demyelinating disorders, degenerative diseases, cerebrovascular accidents, mass lesions, and infectious diseases. The clinical features that point to a diagnosis of MG include the variable nature of the muscle weakness, normal sensation, and normal deep tendon reflexes. The diagnosis can usually be

CLINICAL PEARLS

TELLTALE SIGNS OF MYASTHENIA GRAVIS

- >> Variable muscle weakness
- >> Weakness in cranial nerve distribution
- >> Normal reflexes and sensation

Fig. 64.1 Neuromuscular transmission in normal and myasthenic subjects. With repetitive stimulation there is a reduction in the efficiency of acetylcholine (ACh) release, with a subsequent recovery in efficiency as the train of stimuli continues. Although the endplate potential (EPP) fluctuates at the normal junction, sufficient current is generated to stimulate an action potential of constant magnitude. At the myasthenic junction, however, the amplitude of the EPP in response to a given amount of ACh is reduced. Under conditions of inefficient ACh release, e.g., repetitive stimulation, the minimum current for conduction is not generated, resulting in a profile of action potentials that shows a progressive decline or decrement with subsequent recovery.

confirmed by pharmacologic and electrophysiologic testing. A decremental pattern is characteristically seen following repetitive nerve stimulation (Fig. 64.1) and this pattern is normalized following treatment with the anticholinesterase agent tensilon. Further confirmation rests on detecting anti-AChR antibodies, which are found in 85–90% of patients with generalized disease. In the standard assay, sera are reacted with a nicotinic AChR preparation labeled with ^{125}I - α -bungarotoxin, a snake venom polypeptide that binds irreversibly to the receptor. Bound antibodies are immunoprecipitated by an anti-immunoglobulin reagent or staphylococcal protein A, and the quantity of antibodies detected is expressed in terms of the amount of α -bungarotoxin bound.

ACETYLCHOLINE RECEPTOR STRUCTURE

The nicotinic AChR (nAChR) is a member of a larger family of ligand-gated ion channels. The muscle-type receptor, which is involved in myasthenia, can be further subclassified into mature junctional receptors, and immature, extrajunctional, or denervated receptors. The nAChR at a mature myoneural junction is composed of four subunits, labeled α , β , δ , and ϵ (Fig. 64.2). In fetal muscle and adult denervated muscle or non-junctional membrane, a γ -subunit replaces the ϵ -subunit found in mature innervated muscle endplates. This form of the receptor differs from the mature junctional form by its lower density (500 receptors/ μm^2) and its distribution over most of the surface of the sarcolemma. The immature receptor also has a lower conductance, a longer open time, a more rapid turnover, and a decreased half-life.

The genes for the α -, δ -, and γ -subunits are located on chromosome 2 in humans, and subunits β and ϵ on chromosome 17. There are two

isoforms of the α -subunit, which are generated by alternative splicing.² The larger, which includes an additional sequence of 25 amino acids between exons 3 and 4, is found only in humans and other primates. The subunits of the AChR are homologous to each other and to their counterparts across species, with the greatest conservation of sequence being in the α -subunit. Two α -subunits and one of each of the other subunits are assembled to form an asymmetric hourglass channel spanning the membrane. Each subunit has a large amino-terminus located extracellularly, four transmembrane regions, and a short cytoplasmic tail formed by a loop between the third and fourth transmembrane domains. The receptor appears as a dimer owing to disulfide bonding between the δ -subunits of two receptors. The two α -subunits are not contiguous in each receptor but are separated by another subunit. One ACh-binding site is found on each of the α -subunits around the pair of cysteines at amino acids 192 and 193. The binding of ACh to the α -subunits is believed to engender a conformational change, possibly resulting in rearrangement of charged groups. The binding of ACh to both α -subunits increases the probability of transition of the channel to an open conformation. Binding of curare or α -bungarotoxin to the α -subunits blocks this channel.

In normal innervated neuromuscular junctions there are two forms of the AChR, the predominant form having a long half-life, and a small subset that is rapidly turned over.³ The rapidly turned-over receptors are the precursors of the stable receptors. It is not clear how these two types differ, or how they are regulated. The receptors are concentrated at the top of the folds in the muscle endplate, adjacent to the nerve terminus, at a density of 10 000/ μm^2 . This localization reflects the action of agrin, a nerve-derived synaptic organizing molecule.⁴ The AChRs are organized into clusters by rapsyn, a 43-kDa cytoplasmic protein.⁴ The clustered AChRs are linked to the cytoskeleton by connections between rapsyn and a dystrophin-glycoprotein complex.

Fig. 64.2 The acetylcholine receptor. The subunits of the acetylcholine receptor – α , β , δ , and γ or ϵ – are arranged like barrel staves around the central ion pore. Each subunit winds through the junctional membrane four times (sites M1, M2, M3, and M4). In the unfolded view of the α -subunit, the amino-terminal end of the α -subunit is extracellular, where it is accessible to acetylcholine, which binds at the site shown (amino acids 192 and 193). In myasthenia gravis, autoantibodies may bind to various epitopes of all subunits, but a high proportion of antibodies bind to the main immunogenic region of the α -subunit.

NEUROMUSCULAR TRANSMISSION

When an impulse is transmitted along an axon terminal it results in the release of the neurotransmitter ACh across its presynaptic membrane (Fig. 64.3). ACh diffuses across a 50-nm synaptic cleft, where it interacts with AChRs that are displayed in greatest density at the tops of the junctional folds of the postsynaptic muscle membrane or endplate. This interaction leads to a local depolarization or endplate potential caused by increased membrane permeability to sodium and potassium. The endplate potential is terminated by acetylcholinesterases, which are present in highest concentrations in the synaptic cleft around the junctional folds. If the summation of endplate potentials attains a prescribed threshold it produces an action potential that depolarizes the surrounding sarcolemma and causes muscle contraction. In a healthy individual the arrival of an impulse at the presynaptic membrane of a motor nerve releases considerably more ACh than is required to generate an action potential. This reserve, roughly four times the current needed for propagation of the impulse, is referred to as the safety factor of neuromuscular transmission. Because of the severe reduction in receptor number in MG, the electrical threshold for propagation of an action potential cannot be attained and muscle contraction is prevented. With a less severe reduction in receptor numbers neuromuscular transmission may proceed normally unless the efficiency of presynaptic vesicle release is compromised, as occurs with repetitive use of muscles. The combination of decreasing availability of ACh and the reduced

Fig. 64.3 Schematic representation of the myoneural junction. Vesicles of acetylcholine (ACh) release their contents at active zones across from ACh receptors (AChRs) in response to impulses conducted down nerve axons. ACh diffuses across synaptic cleft and binds to AChRs, with opening of the ion channel and the generation of endplate potential. Action potential is propagated to muscle when sufficient amplitude of summated endplate potentials is attained.

KEY CONCEPTS

INVOLVEMENT OF ANTI-ACETYLCHOLINE RECEPTOR (AChR) ANTIBODIES IN THE PATHOGENESIS OF MYASTHENIA GRAVIS (MG)

- >> Anti-AChR antibodies found in serum of 90% of MG patients
- >> Infants born to myasthenic mothers sometimes develop MG
- >> Immunoglobulin G (IgG) and complement deposited at the postsynaptic junction
- >> Transfer of IgG from MG patients to mice induces neuromuscular blockade

number of receptors accounts for the characteristic decremental nerve conduction pattern seen on electromyograms of patients with MG following repetitive nerve stimulation (Fig. 64.1).

IMMUNOPATHOGENESIS OF MYASTHENIA GRAVIS

Anti-AChR antibodies are detected in 85–90% of MG patients and are responsible for the impaired neuromuscular transmission.⁵ There are many lines of evidence to support this contention. Immunoglobulin G (IgG), along with C3 and the terminal attack complex (C5–C9), is deposited at AChR-containing areas of the postsynaptic membrane, and anti-AChR–AChR complexes can be extracted from the muscles of patients with MG. Transfer of myasthenic serum from mother to fetus, or from human to mouse, results in symptoms or signs of myasthenia in the recipient. Plasmapheresis, which decreases anti-AChR antibody levels, is associated with clinical improvement.

PROPERTIES OF ANTI-AChR ANTIBODIES AND CHARACTERIZATION OF B-CELL EPITOPES

Anti-AChR antibodies are produced by a small subset of B cells in affected people. The frequency of IgG-producing AChR-specific peripheral blood mononuclear cells is estimated to be 1 in 15 000–70 000. IgG anti-AChR-secreting cells are also found in the peripheral blood of healthy volunteers, albeit in much lower numbers. The proportion of immunoglobulin-producing AChR-specific B cells or plasma cells is greater in the germinal centers of hyperplastic thymuses, but still only 1 in 1000–10 000 antibodies produced is AChR-specific. Anti-AChR antibodies are predominantly IgG₁ and IgG₃ but IgG₂ and IgG₄ isotypes have also been found. IgA and IgM anti-AChR antibodies are present in some patients, but never in the absence of IgG anti-AChR antibodies. The IgA and IgM anti-AChR antibodies tend to appear in patients whose disease is of longer duration and greater severity, and in association with high IgG titers.

The pathogenic anti-AChR antibodies in MG are thought to be directed to conformationally dependent structures. Immunization of animals with irreversibly denatured AChR leads to the formation of

anti-AChR antibodies capable of binding to native AChR, but the antibodies are not capable of causing disease. This observation indicates that conformationally dependent epitopes are important in the induction of disease. Many of the anti-AChR antibodies are directed against the α -subunit, particularly to a small region on the extracellular portion referred to as the main immunogenic region (Fig. 64.2). Approximately 60% of the anti-AChR antibodies are directed against this region, which encompasses a set of overlapping epitopes clustered around amino acids 67–76 of the α -subunit.⁶ The reason for the predominant role of the α -chain in the antibody response in myasthenia is not known. Not all disease-producing antibodies in humans or rats appear to be directed to this region. Many patients also have antibodies recognizing the γ -containing embryonic form of AChR. This observation has spawned speculation about a nonmuscle source of sensitization.

ANTI-AChR ANTIBODY LEVELS AND RELATIONSHIP TO DISEASE ACTIVITY

The relationship of anti-AChR antibody and disease activity in MG is complicated. In general, serum levels of anti-AChR antibody or anti-AChR–AChR complexes correlate poorly with disease severity. Among patients within one clinical grade, anti-AChR antibody levels can vary by several orders of magnitude. In addition, approximately 10–15% of patients with clinical MG have no anti-AChR antibody by standard assays. Anti-AChR antibodies are more likely to be present if the disease is generalized or severe, and there is a tendency for higher levels of anti-AChR antibody to correlate with more severe disease. Also, in an individual patient an increase or decrease in anti-AChR antibody levels often accompanies deterioration or improvement, respectively, in clinical activity.

As the quantity of anti-AChR antibodies produced does not fully explain disease severity, studies have also focused on qualitative differences in these antibodies among different patients. These studies, however, have not been able to distinguish properties of anti-AChR antibodies that lead to greater pathogenicity. Differences in specificity and avidity of binding to AChR have not been associated with particular functional effects or disease severity. Anti-AChR antibodies that bind or compete for the same region of AChR can have different functional effects. Anti-AChR antibodies show extensive heterogeneity by isoelectric focusing, but this characteristic also does not correlate with pathogenic potential.

As noted above, 10–15% of MG patients are persistently antibody-negative. Recently a subset of these patients has been discovered to have serum IgG antibodies specific for muscle-specific tyrosine kinase (MuSK).⁷ The prevalence of these antibodies in seronegative patients varies across geographical locales with 60–70%, 40–50%, and 4% reported in patients in the UK (some sera from patients in other European countries), USA, and Taiwan, respectively. Unlike patients with MG and anti-AChR antibodies (see below), most MuSK antibody-positive patients do not have thymic pathology. They tend to be young adult females with bulbar, neck, or respiratory muscle weakness. There is also evidence that some of the so-called antibody-negative patients have anti-AChR antibodies that are not detected by the routine assay systems. For example, plasma from some of these patients can passively transfer a defect in neuromuscular transmission, and disease activity in some seronegative patients improved with plasmapheresis. Anti-AChR antibodies have been demonstrated in some of these patients by rosetting assays

using BC3H1 cells (a mouse tumor cell line that expresses AChR on its surface). Anti-AChR-secreting B cells have also been identified in seronegative patients by immunospot assay. Consistent with this finding, human IgG was demonstrated at the neuromuscular synapse when peripheral blood mononuclear cells from seronegative patients were transferred to severe combined immunodeficiency (SCID) mice. These findings are difficult to reconcile with those from mice administered plasma from seronegative patients. Although these mice had impaired neuromuscular transmission on electromyography, immunoglobulin was not detected at the myoneural junction.

Patients with MG associated with thymoma show distinct patterns of antibody production. Almost all patients with thymoma are anti-AChR antibody-positive and most produce antistriational antibodies.⁸ These antibodies react with titin, a giant filamentous protein of striated muscle. Titin filaments are involved in muscle assembly and contribute to the muscle's ability to recoil following stimulation. Such antistriational antibodies are also found in approximately 50% of the sera of older, nonthymoma MG patients who have thymic atrophy, but are not frequently detected in patients with early-onset disease and thymic hyperplasia. The finding of antistriational antibodies in an MG patient less than 40 years old strongly suggests the presence of thymoma. There is no evidence that antistriational antibodies are involved in muscle weakness.

MG sera also contain antibodies reacting with the ryanodine receptor.⁸ These receptors, which are critically involved in muscle contraction, are Ca^{2+} release channels located in the sarcoplasmic reticulum of striated muscles. Antibodies to ryanodine receptors are found in 50% of MG patients with thymoma, and patients with high levels have a worse prognosis than do antibody-negative MG patients with thymoma. *In vitro* studies have suggested a pathogenic role for these autoantibodies in MG.

Antirapsyn antibodies have been detected in a small subset of MG patients.⁹ Seropositive patients with MG are indistinguishable from seronegative patients with regard to clinical and laboratory features of disease. The presence of this autoantibody specificity is not specific for MG, having been detected in the sera of an occasional multiple sclerosis patient and a majority of the lupus patients tested.

PATHOGENIC EFFECTS OF ANTI-ACHR ANTIBODIES

Complement-mediated damage

The critical problem in MG is the anti-AChR antibody-mediated reduction in the number of nAChRs at the myoneural junction. There are several possible mechanisms by which the anti-AChR antibodies could lead to impaired neuromuscular transmission.¹⁰ Ultramicroscopic studies show marked destructive changes in some endplates, particularly at the peaks of the postsynaptic folds, where AChR is usually present in the greatest concentration. The architecture of the muscle endplate is simplified, with loss of junctional folds and widening of the synaptic cleft that contains membrane debris. C3, C9, and the membrane attack complex are deposited at the muscle endplate, suggesting a role for complement in membrane destruction.¹¹ Indeed, the anti-AChR antibodies in many patients can fix complement *in vitro* when bound to skeletal muscle, and can damage cultured rat myotubes with a resultant decrease in AChR content.

KEY CONCEPTS

EFFECTS OF ANTI-ACETYLCHOLINE RECEPTOR (AChR) ANTIBODIES IN MYASTHENIA GRAVIS PATHOLOGY

- >> Reduced number of receptors
- >> Widening of the synaptic cleft
- >> Distorted geometry of the synaptic membrane

Mechanism of damage

- >> Complement-dependent damage to muscle endplate
- >> Enhanced rate of AChR degradation
- >> Block cholinergic binding sites

Although antibody-directed complement-mediated destruction is important in the pathophysiology of MG, it is not the entire story. The rapid clinical improvement in MG following certain therapeutic interventions and the lack of destructive changes in many neuromuscular junctions of symptomatic areas despite prominent immunoglobulin deposition suggest that a more readily reversible process is also likely to be involved in the neuromuscular block.

ACCELERATION OF AChR DEGRADATION

In vitro and *in vivo* studies have shown that anti-AChR antibodies can accelerate the rate of degradation of extrajunctional and junctional receptors, respectively.¹² This reaction is complement-independent and is due to the endocytosis of AChRs via shallow depressions, presumably clathrin-coated pits. Other membrane receptors are not affected. Both stable and rapidly turned-over receptors appear to be affected, thereby explaining the greater than expected antibody-mediated loss of AChRs observed at neuromuscular junctions. The reaction requires cross-linking of adjacent AChRs, as it can be mediated by F(ab')_2 fragments, but not Fab fragments, of anti-AChR antibodies. The effect of antibody on the synthesis of new AChR is controversial.

RECEPTOR BLOCKADE

The inhibition of ACh binding has been assessed by studying the effects of MG serum on the binding of the neurotoxin α -bungarotoxin to AChRs. Such blocking antibodies are found in a variable number of MG sera. Blockade has been generally attributed to steric hindrance of the ligand-binding site, rather than direct binding to the ACh-binding site.¹³ The importance of these antibodies in the pathophysiology of MG remains unclear. However, in one study the functional ability of an individual serum to accelerate degradation and cause blockade of AChRs paralleled most closely the clinical status of the patient. The *in vivo* significance of such antibodies has also been demonstrated by passive transfer of certain rat monoclonal anti-AChR antibodies into chicks. Complete paralysis was observed within 1 hour of the transfer, presumably before there was time for complement-mediated damage. In MG patients it has been reasoned that such blocking antibodies could further

diminish synaptic function that is already decreased owing to complement-mediated damage or accelerated receptor degradation. This could result in acute clinical deterioration or a rapid clinical improvement after plasmapheresis, before the repair of damaged membrane and regeneration of new AChRs.

■ ROLE OF T CELLS ■

An overwhelming body of data indicates that anti-AChR antibody production in MG patients and rodents with experimental autoimmune MG (EAMG) is dependent on the activity of CD4 T cells. Researchers have used freshly isolated CD4 T cells, T-cell lines, and T-cell clones stimulated with AChR purified from the electric organs of *Torpedo californica* (T-AChR), recombinant human AChR, human AChR concentrated on immunomagnetic beads, and synthetic AChR peptides. Most of the T cells derived from MG patients have responded to the complete AChR or the α -subunit, but responses to the δ -, ϵ -, and γ -subunits have also been demonstrated.¹⁴ Unlike EAMG, a T-cell immunodominant epitope has not been found in humans. However, T cells from most patients recognize a limited number of AChR sequences. In an individual patient, T cells reactive with a particular AChR epitope can show limited T-cell receptor (TCR) V β usage, but the same TCR V β usage has not been observed for different patients. A range of major histocompatibility complex (MHC) class II molecules can present AChR epitopes. This is not surprising, given the degenerate binding capabilities of MHC molecules needed to present an extremely large and diverse group of peptides to the immune system. T cells from normal controls respond to some of the same epitopes to which MG patient's T cells respond, albeit in smaller numbers and less vigorously.

■ EXPERIMENTAL AUTOIMMUNE MYASTHENIA GRAVIS ■

The serendipitous discovery that rabbits injected with purified AChR developed not only anti-AChR antibodies but signs of MG provided the evidence for the pivotal role of antibodies in this disease, and paved the way for the development of an experimental model of human MG.¹⁵ EAMG has been studied in a number of different animal species.¹⁶ It is generally induced by immunizing animals with T-AChR that is emulsified in adjuvant. Disease may also be passively transferred by immunoglobulin from affected animals or from patients with myasthenia. Animals suffer from fatigue, hypoactivity, weight loss, paralysis, difficulty in breathing, and dysphagia; these signs are reversible with anticholinesterases. There is a decremental response to repetitive nerve stimulation on electromyography in EAMG as in MG. Anti-AChR antibodies are primarily directed against the main immunogenic region (Fig. 64.2) and are deposited along with complement at the muscle endplate. Similar to the pathology in humans, there is simplification of the muscle endplate and a loss of AChR content of muscles in the experimental disease. A major difference between the induced rodent models of EAMG and spontaneous human MG is the absence of thymic pathology in the former.

In murine models there are disease-resistant and disease-susceptible strains. The MHC determines this susceptibility in part, with specific H₂

alleles associated with susceptibility or resistance. However, even in the high-responder strains only 50–70% of immunized animals manifest disease. This lack of concordance remains to be fully explained. Differences in the level of complement activation and the physiologic safety factor of neuromuscular transmission may partly account for the variability in disease expression.

Most immunized animals demonstrate anti-AChR antibodies whether or not they develop EAMG. Induction of pathogenic antibody production requires the integrity of the three-dimensional structure of the receptor, as immunization with denatured AChR elicits antibody production but not disease, even in susceptible animals. Anti-AChR antibody levels correlate with anti-AChR–AChR complexes and with the AChR content of the muscle, but not with clinical disease severity. No characteristic feature distinguishing disease-producing and nonpathogenic autoantibodies has been defined. Antibodies in rats with and without disease are predominantly of the same immunoglobulin isotype and subclass, express similar clonotypic heterogeneity, and show similar avidities. The percentage of antibodies that recognize the native receptor (as opposed to the foreign eel receptor immunogen) is low (0.2–2%), but similar between the symptomatic and the asymptomatic mice. The percentage of antibody directed against the main immunogenic region of AChR is also similar. The antibodies that develop in asymptomatic animals can bind and cause a decrease in receptor half-life, as well as those that develop in paralyzed animals. In fact, EMG abnormalities can be demonstrated in mice that appear disease-free.¹⁷ An analogous situation in humans may be the high frequency of single-fiber EMG abnormalities in asymptomatic family members of patients with MG. Importantly, antibodies from affected animals will cause disease in resistant strains, indicating that disease differences between strains is not caused by differences in the AChR receptor itself.

Although EAMG is mediated by autoantibodies, it is a T-cell-dependent process. Examination of T-cell responses in rats and mice has shown that EAMG requires the action of CD4 T cells. These cells recognize immunodominant T-cell epitopes located on the α -subunit.¹⁶ The T-cell responses to the immunodominant epitope in rats involve a variety of TCRV β and J β gene segments. However, in susceptible C57BL/6 mice there is a predominant use of the TCRV β 6 family in the CD4 T-cell response.¹⁶ CD4 T cells in susceptible and resistant strains recognize different immunodominant AChR α -chain epitopes.¹⁸

Early reports suggested that AChR-reactive T-cell clones did not fit neatly into T-helper 1 (Th1) and Th2 subsets. However, later studies suggested that interferon- γ (IFN- γ) production by Th1 cells is essential for the development of disease and that interleukin-4 (IL-4) may subserve a protective role.^{16,19} In addition to IFN- γ , tumor necrosis factor- α (TNF- α), IL-6, IL-12, IL-18, IL-1, IL-5, and IL-10 have been reported to promote the development of EAMG.

The roles of co-stimulatory factors have also been investigated in EAMG. Gene knockout studies have implicated roles for both B7.1 and ICOS in the development of EAMG.^{20,21}

■ THE THYMUS IN MYASTHENIA GRAVIS ■

Several lines of evidence have implicated the thymus in the pathogenesis of MG.

PATHOLOGY

Early observations from autopsy material and later analyses of thymectomy specimens indicated that the thymus is pathologically abnormal in 80–90% of MG patients.²² The majority of patients (65–75%) have thymic follicular hyperplasia. This histologic picture is seen most frequently in women with a relatively early disease onset and with human leukocyte antigen (HLA)-B8 and DR3 haplotypes. The architecture of the hyperplastic thymus is generally preserved, with well-demarcated cortical and medullary regions. However, the medulla is crowded by numerous germinal centers that display the architectural features and cellular constituents of germinal centers in the secondary follicles of peripheral lymph nodes from normal individuals. Although these germinal centers in patients are generally thought to occupy an intraparenchymal position, some observers feel that they may actually lie extraparenchymally in the perivascular space. The appearance of thymic germinal centers is not unique to MG. They have been observed in the thymus of healthy subjects who have died suddenly from traumatic injury, and in autopsy specimens of patients with systemic lupus erythematosus, thyrotoxicosis, and multiple sclerosis. Nevertheless, they are widely regarded to be larger and more numerous in patients with MG.

Patients with MG and associated thymomas tend to be older and show no gender predominance or HLA associations. Histologic sections show neoplastic epithelial cells admixed with thymocytes and a loss of the normal corticomedullary definition. The affected epithelial cells belong to the cortical epithelial compartment, and the thymocytes have the immunophenotypic properties of normal immature cortical thymocytes.

CLINICAL

The demonstration of thymic pathology prompted empiric trials of thymectomy in patients with MG. Although no controlled study has been performed, there is general agreement that removal of the thymus, particularly in young patients with follicular hyperplasia, leads to clinical improvement. This topic is considered in more detail in the discussion on therapy later in this chapter.

INTRATHYMIC AChR

For some time there has been evidence that nAChR is expressed in the thymus.^{22, 23} This finding, in conjunction with the thymic pathology described above, has raised the hypothesis that thymic expression of AChR may be involved in the initiation or perpetuation of the autoimmune response in MG. At the protein level, the AChR α -chain is expressed on thymic myoid cells and epithelial cells. Most of the current evidence is consistent with the expression of a fetal receptor on myoid cells and an adult receptor on thymic epithelial cells. In addition, an epitope localized to residues 373–380 of the AChR α -chain cytoplasmic domain has been detected on neoplastic epithelial cells of thymomas and thymic carcinomas, and is most often seen in thymomas associated with MG. This epitope is also found in smaller amounts on normal thymic medullary cells. The source of the epitope is not AChR but a cross-reactive protein with a molecular weight of 153 kDa.²⁴ The overexpression of this protein in thymomas can trigger an anti-AChR antibody response, leading to the development of MG.

KEY CONCEPTS

PATHOGENIC ROLE OF THE THYMUS IN MYASTHENIA GRAVIS

Clinical

Immunological

- >> 65–75% of patients have follicular hyperplasia; 10% have thymomas

Pathological

- >> Nicotinic acetylcholine receptor (nAChR)-reactive T and B cells localized in thymus
- >> nAChR expressed on cells within thymus

Studies relying on molecular probes of AChR expression indicate that both major isoforms of the α -subunit are expressed in human thymus.^{23, 25} The smaller P3A⁻ isoform is present in approximately a fivefold excess in both MG and control thymic tissue,²⁵ which differs from the equivalent expression of these isoforms in control and MG muscle. These observations suggest that the expression of mRNAs encoding the P3A⁻ and P3A⁺ isoforms is regulated differently in human thymus compared to muscle. As the same disproportionate expression of P3A⁻ was observed in control and MG thymus, the differential pattern of expression observed in thymus relative to muscle is probably not a manifestation of thymic pathology in MG. Rather, this pattern may reflect control processes that are unique to these two distinct tissue compartments. It is currently not known whether the disproportionate expression of P3A⁻ and P3A⁺ isoforms has pathogenic significance. Notably, the expression of both P3A⁺ and P3A⁻ mRNAs is increased in MG thymus relative to control thymus. This finding parallels that reported for skeletal muscle, where AChR mRNA expression is greater in MG muscle than in control muscle. The finding of increased AChR α mRNA expression in MG thymus may represent an attempt to compensate for the destructive action of locally secreted anti-AChR antibodies. The increased AChR mRNA expression may also reflect the antecedent action of other local environmental factors, e.g., cytokines.

In this regard, we have found that IFN- γ enhances the expression of AChR α mRNA on human thymic epithelial cells *in vitro*.²⁵ It is known that IFN- γ upregulates the expression of MHC class II antigens on thymic epithelial cells.^{26, 27} The dual effect of IFN- γ on AChR α and MHC antigens raises the possibility that this cytokine, and perhaps others, may alter expression of thymic AChR α *in vivo* in a manner that leads to the development or perpetuation of MG. Evidence supporting the potential contribution of IFN- γ comes from recently reported microarray data showing upregulation of IFN- γ inducible genes in hyperplastic MG thymus.²⁸

Sequencing of P3A⁺ and P3A⁻ cDNA clones recovered from control and MG thymus indicates that they share the same nucleotide sequence as their respective counterparts at the myoneural junction.^{23, 29} Therefore, unless there are posttranslational changes, the structures of the AChR proteins expressed in the thymus and the periphery are likely to be identical. These results provide a structural basis for proposing that an

immune response directed at thymic nAChR α is indeed responsible for initiating or perpetuating disease.

IMMUNOLOGIC

From an immunologic standpoint, the MG thymus has unique features that could reflect pathogenic involvement and help explain some of the histologic abnormalities.²² Although B cells and Ig-secreting cells are rare intramedullary inhabitants of normal thymus, they are increased in cell suspensions of MG thymus, particularly hyperplastic thymus relative to control thymus (obtained from subjects undergoing elective cardiotoracic surgery). When stimulated *in vitro* with the polyclonal B-cell activator pokeweed mitogen, both MG and normal thymus cell suspensions produced surprisingly large amounts of immunoglobulin, with the IgG isotype greatly exceeding IgM.

There has been great interest in determining whether the heightened B-cell activity in MG thymus reflects local immune events. Single-cell suspensions from thymus of MG patients with follicular hyperplasia secrete anti-AChR antibody *in vitro* without addition of B-cell activators.²² However, the thymic B-cell repertoire also includes anti-influenza specificity and antitetanus toxoid specificity. The latter is only detected when patients are booster-immunized to tetanus toxoid 3–4 weeks prior to thymectomy. Thus, the B-cell repertoire in the MG thymus may reflect systemic as well as local immune events.

AChR-reactive CD4⁺ T cells have been detected and propagated as long-term lines and clones from MG thymus (both thymoma and hyperplasia), but not from normal thymus. These antigen-specific T cells seem to be enriched in the thymus relative to the blood of the same MG patient. Migration of T cells reactive to foreign antigen into the thymus is known to occur.³⁰ Therefore, it is not clear whether AChR-reactive T cells in MG thymus are sensitized in the periphery with subsequent intrathymic localization, or are sensitized *in situ*.

In addition, hyperplastic MG thymus showed increased numbers of IL-1 and IL-6-producing cells. These cells were found largely in the perifollicular areas and connective tissue adjacent to the septa of disrupted cortex. Cells producing IL-2 were less prominent and largely confined to perifollicular areas. This distribution of cytokine production was not seen in normal thymus or in hyperplastic lymph nodes.

Together, the above studies indicate that MG thymus contains the cellular constituents necessary for an immune response directed against AChR. These include AChR-reactive B cells and helper T cells, cytokines that can facilitate B-cell activation, chemokines that attract immigrant lymphocytes, and a local source of the autoantigen. MG thymus also appears to contain normal numbers of CD4⁺CD25⁺ regulatory T cells.³¹ However, these cells are characterized by reduced expression of the transcription factor FOXP3 and decreased suppressive function. Such impaired thymic regulatory T-cell function could impede the development or maintenance of T-cell tolerance to locally expressed AChR. Nevertheless, it is still not known whether autoimmunization occurs in the thymus with spillover to the myoneural junction, or whether the thymic pathology is causally related to the pathogenesis of MG. As previously mentioned, thymic pathologic changes are not typically seen in the thymus of rodents with actively or passively induced MG. Thus, the pathologic changes seen in MG thymus are not secondary to the systemic autoimmune response and may be linked to the etiopathogenesis of this disease. The trigger for the putative intrathymic sensitization remains to be determined.

■ ETIOLOGIC FACTORS ■

GENETIC FACTORS

Similar to most autoimmune diseases, the MHC represents an important genetic susceptibility locus for the development of MG. Studies indicate that the MHC haplotype with HLA-B8, DR3, and DQ2 is associated with early-onset MG and hyperplastic thymus in Caucasian individuals. An association with HLA-B7 and DR2, although weaker, has also been described for patients with onset of MG after the age of 40 years associated with atrophic thymic histology. In murine studies the MHC class II molecules I-A^b and I-E^k have been associated with susceptibility to EAMG.¹⁶ In EAMG the permissive MHC class II molecules are capable of binding AChR peptides that are recognized by antigen-specific CD4 T cells.

Studies have also addressed the potential genetic contributions of other immune system-related genes in the pathogenesis of MG. An association has been reported for a particular IL-1 β allele and MG³² and increased serum levels of this cytokine have been reported. This was most pronounced in patients who lacked disease-susceptible HLA genes. Several groups have reported an association between MG and the presence of particular TNF- α polymorphisms.^{33,34} Polymorphisms in the IL-10 promoter region have been reported to be associated with distinct patterns of thymic histology.³⁵ No correlations have been made between IL-4 alleles and MG. Finally, allotypic markers on IgG and Fc γ RIIa receptors have been associated with the coexistence of MG and thymoma.

EXOGENOUS FACTORS

Whether or not sensitization to AChR occurs in the thymus or the periphery, the stimulus for this autoimmune response remains a conundrum. Moreover, it remains to be determined whether the stimulus is self-antigen (AChR) or a foreign antigen that mimics the receptor's molecular structure. In this regard, several examples of molecular mimicry between AChR α chain and other molecules have been reported. Studies carried out with certain monoclonal anti-AChR antibodies demonstrated epitope sharing between the receptor and several bacteria, including *Klebsiella pneumoniae*, *Escherichia coli*, *Proteus vulgaris*, and *Yersinia enterocolitica*. However, for the most part no difference was observed in the binding of polypeptides from these organisms by either MG patient or control sera. A computer search of protein banks revealed a sequence homology between AChR α chain and a short peptide in herpes simplex glycoprotein D, although the significance of this finding is unknown. Finally, similarities were reported between idiotypic determinants on anti-AChR antibodies and antibodies reactive with α 1,3 dextran. Interestingly, anti-dextran antibodies were detected in approximately 13% of MG patients but rarely in normal controls.³⁶ α 1,3 Dextran is found in the cell walls of several common enteric pathogens and thus represents a potential ubiquitous source of immunogen. This type of idiotypic network connectivity led the investigators to postulate that an unregulated anti-idiotypic response to anti- α 1,3 dextran antibodies might lead, in certain individuals, to an anti-AChR antibody response. Unfortunately, there has been no follow-up to these observations.

A striking association has been reported between the development of MG and treatment with the drug penicillamine,^{37,38} particularly in individuals with HLA DR1. MG developed in patients with rheumatoid

arthritis and patients with Wilson's disease treated with this agent. After discontinuation of penicillamine, resolution of MG symptoms was reported in some patients but not others. Penicillamine treatment was associated with the development of anti-AChR antibodies that appeared to have the same type of specificity profile as found in idiopathic myasthenia. Additional evidence suggests that penicillamine may directly interfere with neuromuscular transmission. Although penicillamine has been shown to have diverse effects on the immune response in the normal host, and has reactive sulfhydryl groups capable of modifying self-antigens, its role in the development of MG remains to be determined.

TREATMENT OF MYASTHENIA GRAVIS

Therapeutic intervention in MG usually proceeds in a stepwise manner, beginning with anticholinesterase agents.³⁹

ANTICHOLINESTERASES

Anticholinesterases are the mainstay of treatment. These agents protect ACh from hydrolysis by cholinesterase, thereby increasing the amount of neurotransmitter and the number of contacts with the reduced number of receptors at the postsynaptic junction. This in turn raises the probability of attaining the necessary threshold for neuromuscular transmission. In addition, some of the anticholinesterase agents have a direct agonist effect at the postsynaptic junction. The three most popular agents in this group are neostigmine bromide (prostigmine), pyridostigmine bromide (mestinon), and ambenonium chloride (mytelase). Although there are only slight differences between these agents, mestinon remains the most commonly used. It has an onset of action of 30–60 minutes, peak action at about 2 hours, and loss of activity occurring after 4 hours. The drug is usually initiated at a dose of 60 mg every 3–4 hours and increased if necessary in 30–60-mg increments. Additional benefit is not usually seen at doses higher than 240 mg every 3–4 hours or 120 mg every 2 hours. It is important to individualize the dosing schedule for each patient according to needs. For example, the patient with bulbar symptoms should be instructed to take anticholinesterase 30 minutes to 1 hour before meals. Adverse effects of these agents are due to excessive stimulation of nicotinic and muscarinic receptors. The nicotinic side effects include fasciculations, muscle cramps, and increased weakness. Muscarinic side effects include

diarrhea, abdominal cramps, palpitations, increased sweating, and nasal and bronchial secretions. Adding atropine or an atropine analog to the regimen can minimize the latter group of reactions. This provides a cushion for increasing the amount of drug, and hence, its effect at the postsynaptic junction. Auxiliary drugs that have been purported to have a salutary effect on neuromuscular transmission are ephedrine and xanthine derivatives (theophylline), which are thought to increase the presynaptic release of ACh. The minimal effect of their added benefit has not warranted their common usage.

THYMECTOMY

Another mainstay in the therapy of the adult with generalized MG is thymectomy.³⁹ The benefit is greatest in younger patients and those with thymic hyperplasia, although many centers include older patients as well. Although no controlled study has ever been carried out, the accumulated experience indicates that thymectomy is associated with an excellent outcome, measured as either remission or an improvement in clinical symptoms. In one study 90% of patients were asymptomatic or in complete remission within a few years of thymectomy, and 46% were off all medications. With improvements in preoperative care, anesthesia, surgical technique, and postoperative care, thymectomy has become a very safe procedure, but its value and safety in children and older patients are less well established. There is still some controversy over what represents the best surgical procedure, although the trans-sternal approach is the choice in most centers. Unlike the transcervical approach, it is less likely to be complicated by residual thymic tissue. The mechanism responsible for the salutary effect of thymectomy remains to be elucidated. No obvious effects on immunoregulatory mechanisms have been demonstrated, although anti-AChR titers tend to fall months after the procedure. Thymectomy is also the recommended treatment for patients of all ages suspected of having thymoma.

CORTICOSTEROIDS

Corticosteroids are used in patients with generalized MG who fail to respond to anticholinesterase agents or thymectomy, and in patients needing optimization of their clinical condition in preparation for thymectomy. They are generally not used as a first-line agent to replace thymectomy. They are also used in patients with ocular myasthenia who fail to respond to anticholinesterases. Corticosteroids are initially given on a daily basis, with therapy begun in hospital. This cautious approach is followed because of the fear of clinical deterioration that occurs in some patients during the introduction of corticosteroids. Because of this concern, some groups advocate starting patients on alternate-day therapy, which is not typically associated with clinical deterioration and can be carried out on an outpatient basis. Daily corticosteroids are usually started in patients with generalized MG at a dose > 1 mg/kg prednisone. Patients should be continued on this dose until clinical improvement is maintained for several days, and then gradually weaned on to alternate-day therapy. With improvement sustained over several months, an effort should be made to reduce the dose (usually in 5-mg decrements) administered on the alternate day. Although a recent Cochrane review underscored the dearth of controlled trials, the improvement rate is generally estimated to be 60–90%.⁴⁰ Complete remission is rare and most patients will require some dose of steroids indefinitely. The physician should be

alert to the possibility that anticholinesterase requirements may decrease as the patient responds to corticosteroids.

PLASMAPHERESIS

Plasmapheresis has enjoyed popularity since its introduction as an auxiliary treatment modality in 1976, particularly as a temporizing measure.⁴¹ It appears to be most beneficial in patients in myasthenic crisis and in those experiencing progressive deterioration despite treatment with anticholinesterases and corticosteroids. Plasmapheresis has also proved to be useful in preparing patients for thymectomy whose course is complicated by involvement of the bulbar and respiratory musculature. Such patients may also require short-term plasmapheresis during the postoperative period. Although there are no hard and fast rules, the average exchange is 1–2 l/day for 7–14 days. Improvement is usually observed within a few days of concluding the treatment course, although patients in crisis often benefit more quickly. The mechanism of action most likely involves the removal of the pathogenic autoantibody, as a reduction in titer of anti-AChR antibody correlates with clinical improvement. However, it is also possible that the removal of other phlogistic humoral factors contributes to clinical efficacy.

IMMUNOSUPPRESSIVE AGENTS

Immunosuppressive drugs have been tried primarily in patients who have failed treatment with anticholinesterases, thymectomy, plasmapheresis, and corticosteroids.⁷ Most of the experience has been obtained with azathioprine, which has strong anti-inflammatory effects as well as immunosuppressive activity. The dose of azathioprine has varied between 1 and 3 mg/kg per day, with improvement seen between 5 and 20 weeks. The drug is usually started at a lower dose and escalated weekly to achieve the maintenance dose. Patients should be followed with complete blood counts, particularly during the initiation of therapy, as azathioprine has a suppressive effect on the bone marrow. A white blood cell count below $2500\mu\text{m}^3$ or a neutrophil count below $1500\mu\text{m}^3$ should prompt a reduction or termination of the dosage. The results of a randomized double-blind placebo-controlled trial indicated that the addition of azathioprine (2.5 mg/kg) to alternate-day prednisolone was associated with a reduction of the prednisolone dose, fewer treatment failures, longer remissions, and fewer side effects.⁴² There is considerably less experience with cyclophosphamide, another powerful immunosuppressive agent. It is associated with more adverse effects and does not appear to offer any significant advantage. Methotrexate has been used in some uncontrolled studies but there is no information to indicate that it is more efficacious or safer than azathioprine and its onset of action may take as long as several months. As is true for corticosteroid therapy, it is the rare patient who enjoys a permanent remission following institution of immunosuppressive therapy, and those who show some improvement often require treatment indefinitely.

Cyclosporine, a potent immunosuppressive agent, has been investigated because it interferes with IL-2-mediated T-cell proliferation and thus would be expected to interfere with the generation of T cells that would “help” the anti-AChR antibody response.⁷ A recent retrospective study suggested cyclosporine provided benefit in patients whose disease was refractory to corticosteroids and azathioprine. Serious renal toxicity and treatment withdrawal, which plagued earlier studies, were reduced by careful selection of patients. In a 12-month European trial, cyclosporine

A appeared to be as efficacious as azathioprine in producing clinical improvement. Tacrolimus has a similar mechanism of action to cyclosporine A. When used in low dosage, it has proved as effective as cyclosporine A as a corticosteroid-sparing agent with fewer side effects.

Mycophenolate mofetil is another immunosuppressive agent that affects both T and B cells. This agent has now been used in sufficient numbers of MG patients to conclude that it is effective 70–75% of the time, although probably less so in refractory MG.⁷ It has an acceptable safety profile with adverse effects largely related to gastrointestinal intolerance. Benefit may require many weeks of administration.

INTRAVENOUS IMMUNOGLOBULIN

The potential utility of intravenous immunoglobulin (IVIG) was suggested by several uncontrolled trials.⁴³ Interest in the use of this agent grew out of its demonstrated efficacy in other autoimmune diseases, most notably autoimmune thrombocytopenia. IVIG has generally been administered at a dose of 2 g/kg over 2–4 days, although a recent controlled study suggested that 1 g/kg administered on one day was as beneficial as the standard higher dosing.⁴⁴ The results of these trials suggest that IVIG therapy can be associated with rapid clinical improvement in some patients, independent of whether they had undergone thymectomy or were being treated concurrently with corticosteroids or immunosuppressive agents. In some patients improvement was sustained over a period of several weeks. The mechanism(s) of this apparent salutary effect is unknown; improvement was not always accompanied by a consistent reduction in anti-AChR antibody titers.

POSSIBLE FUTURE THERAPEUTIC OPTIONS

There are a number of possible experimental avenues of approach that have been spawned by studies in EAMG. These are aimed at interrupting the sensitization process of helper CD4⁺ T cells, interrupting their effector function, or interdicting the action of downstream action of proinflammatory molecules. Studies directed at CD4⁺ T-cell-orchestrated responses include blocking the presentation of immunogenic AChR peptides by antigen presenting cells with nonimmunogenic forms of peptides, impeding activation by inhibitors of the co-stimulatory molecules CD28 and ICOS, the induction of anergy or apoptosis of AChR-reactive T cells, and suppression of AChR-specific Th1 responses by the induction of regulatory T cells or NKT cells, recently shown to be essential for the development of AChR-specific regulatory T cells.⁴⁵ In addition, inhibition of the cytokines TNF or IL-1 by anti-TNF reagents and an IL-1 receptor antagonist, respectively, have shown efficacy in EAMG.

Two biologics that have begun to receive attention in clinical MG trials are rituximab and etanercept. The former is a monoclonal antibody specific for CD20, a protein expressed on B lymphocytes. The latter is a fusion protein consisting of the extracellular ligand-binding portion of the human p75 TNF receptor linked to the Fc portion of human IgG₁. Rituximab, developed as a therapeutic for B-cell malignancies, has shown efficacy in a number of autoimmune disorders, including some in which T cells, rather than B cells, are regarded as the principal effector mechanism. Anecdotal reports of improvement of MG following administration of rituximab provide a basis for further

exploring its utility of this autoimmune disease. Etanercept also appears promising as a type of immunomodulatory agent in MG. However, a recent trial suggested that patients most likely to benefit are those with low plasma IL-6 and IFN- γ .⁴⁶

Multiple sclerosis

Irene Cortese, Henry F. McFarland

65

Multiple sclerosis (MS) is an inflammatory, demyelinating, relapsing or progressive disorder of the central nervous system (CNS) and is a major cause of disability in young adults. MS usually presents between 20 and 40 years of age and at least 350 000 individuals in the USA alone are affected with MS. Pathologically MS is characterized acutely by multifocal areas of demyelination, loss of oligodendrocytes, and astrogliosis with relative preservation of axons. However, many chronic lesions and some acute lesions are now known to have significant axonal damage. Further, involvement of gray matter is now known to be common, as are diffuse pathological changes throughout the white matter. The etiology of MS remains unclear, but current data suggest that the disease develops in genetically susceptible individuals exposed to environmental triggers. The long-favored hypothesis in MS implicates autoreactive T cells generated in the periphery that access the CNS, where they persist and induce an inflammatory cascade that results in the injury of previously normal neural tissues.

Clinically, MS most often presents as a relapsing remitting disease (relapsing remitting MS) slowly evolving into a course associated with progressive accumulation of disability (secondary progressive MS). In a small number of cases the disease begins with progression independent of acute relapses (primary progressive MS).

KEY CONCEPTS

- >> Multiple sclerosis disease course can be relapsing remitting, secondary progressive, primary progressive, or relapsing progressive
- >> Typical relapses are characterized by gradual-onset focal neurological deficits with spontaneous improvement over weeks to months
- >> Typical symptoms include sensory changes, weakness and loss of dexterity, decrease in visual acuity, double vision, difficulty with coordination or balance

CLINICAL PRESENTATION AND CLASSIFICATION

MS can cause a wide variety of clinical features. The course of the illness, which is also variable, represents an important consideration in the diagnosis of MS.¹

Sensory symptoms are the most common presenting symptoms in MS (21–55%) and ultimately develop in nearly all patients. These present as loss of sensation, paresthesias, dysesthesias, and hyperesthesias that can occur in any distribution. A large proportion of MS patients have persistent sensory loss, usually consisting of diminished vibratory and position sensation in the distal extremities.

Motor symptoms are the presenting manifestation of MS in 32–41% of all cases, although their prevalence in long-standing MS is higher than 60%. Pyramidal tract dysfunction causes weakness, spasticity, loss of dexterity, and hyperreflexia.

In 14–23% of patients, the initial symptom of MS is optic neuritis (ON); however more than 50% experience an episode of ON during their lifetime. Clinically the patient presents with visual loss in one eye that evolves over a few days, often accompanied or preceded by periocular pain, especially with eye movement. Most patients begin to recover within 2 weeks, with significant visual recovery being common.

Cerebellar involvement is frequent during the course of MS with manifestations that include dysmetria, dysidiadochokinesia, telekinetic tremor, dysrhythmia, breakdown of complex motor movements, and loss of balance.

Urinary urgency, frequency, and urge incontinence (due to detrusor hyperreflexia or detrusor sphincter dyssynergia) are common in MS patients, with the combined incidence of bowel and bladder dysfunction in MS being higher than 70%. Symptoms of bladder dysfunction may be transient in the setting of a relapse but are often persistent.

Internuclear ophthalmoplegia, caused by a lesion in the medial longitudinal fasciculus, is the most common cause of diplopia in MS patients.

Cognitive disorders are present in 40–70% of MS patients.² The signs can be subtle and may therefore be missed on a standard mental status examination. The pattern of cognitive decline is characterized by decrease

of episodic memory, processing speed, verbal fluency, and difficulty with abstract concepts and complex reasoning.

Affective disorders, including anxiety and depression, are more frequent in MS patients than in the general population, with depression being found in nearly 75% of patients.

Fatigue is one of the most important sources of disability in MS, occurring in over 75% of patients during the course of their disease.

Uhthoff's phenomenon is a transient worsening of symptoms that frequently follows exercise or elevation of body temperature. These episodes resolve when the body temperature returns to normal or after a period of rest. Fever can similarly induce worsening of symptoms that can be confused with a relapse. Paroxysmal symptoms, characterized by brief duration (seconds to minutes) and frequent recurrence, occasionally dozens of times per day, are common in MS. Typical examples include trigeminal neuralgia, the occurrence of which in a person younger than age 40 is suggestive of MS; and transient sensory symptoms usually precipitated by neck flexion and described as an electrical or tingling sensation that travels down the spine or into the extremities, known as Lhermitte's sign.

Multifocal CNS involvement with recurrent relapses and remissions, and/or slowing progression of neurological deficits are characteristic of MS. A single episode of neurological dysfunction, often called clinically isolated syndrome (CIS), can be suggestive of MS, if other reasonable causes are excluded. This is particularly true of episodes following the typical time course of a relapse with progression over less than 2 weeks (usually days), with or without a period of stabilization, and improvement or resolution (often over months).

Four courses of MS are generally recognized: relapsing remitting, secondary progressive, primary progressive, and progressive relapsing³ (Fig. 65.1). During the relapsing remitting phase of MS, neurological sequelae from relapses can persist but patients do not worsen between the episodes of acute neurological dysfunction.

Typically, after an initial presentation characterized by a relapsing remitting course, patients evolve into a secondary progressive phase of the disease. The word 'progression' has been defined as continuous worsening of neurological impairment over at least 6–12 months.⁴ An international panel defined secondary progressive MS as an 'initial relapsing remitting disease course followed by progression with or without occasional relapses, minor remissions and plateaus.'³ A reasonable estimate of the median time from relapsing remitting MS onset to secondary progression is about 19 years.⁴ In primary progressive MS, patients present with insidious disease and steady progression from the onset. A progressive relapsing course denotes a disease course in which patients continue to have acute exacerbations of disease, but exhibit steady progression of neurological decline between these episodes.

Other terms used to describe the course of the disease but for which there is no consensus regarding their definition include benign MS, which refers to patients who have had MS for a long time but have little

or no disability; and malignant MS, defined by disease with a rapid progressive course, leading to significant disability in multiple neurologic systems or death in a relatively short time after disease onset.³

There are several other CNS inflammatory demyelinating conditions whose relationship to MS is not entirely clear. These include an acute

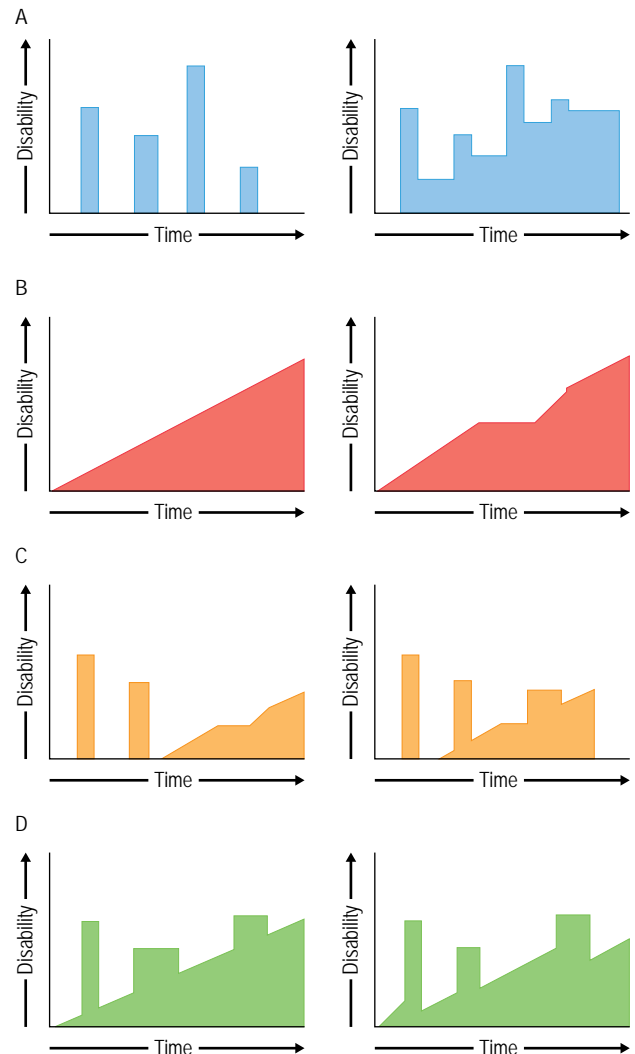

Fig. 65.1 Multiple sclerosis (MS) clinical course definitions.

(A) Relapsing remitting (RR) MS is characterized by clearly defined acute attacks with full recovery (left) or with residual deficit upon remission (right). Between relapses patients are clinically stable. (B) Primary progressive (PP) MS is characterized by progression of disability from onset, without plateaus or remissions (left) or with occasional plateaus and temporary minor improvements (right). (C) Secondary progressive (SP) MS begins with an initial RR course, followed by progression at a variable rate (left) that can include occasional relapses and minor remissions (right). (D) Progressive relapsing (PR) MS shows progression from onset but with clear acute relapses with (left) or without (right) full recovery.

KEY CONCEPTS

- >> Diagnosis of multiple sclerosis requires demonstration of dissemination in time and space, based on clinical presentation alone or in combination with magnetic resonance imaging, cerebrospinal fluid analysis, and visual evoked potentials

form of MS or Marburg variant, which is characterized by a severe, monophasic course with progression to death due to brainstem involvement or mass effect with herniation.

Balo's concentric sclerosis, which from a clinical perspective typically presents with a fulminant course similar to the Marburg variant is distinguished by its unique pathology, described in more detail below, characterized by large demyelinated plaques with alternating rings of myelin preservation and myelin loss.

MS can occasionally present as a mass lesion that can be difficult to distinguish from a brain tumor; this variant is known as tumefactive MS. Generally the diagnosis is made by biopsy that ultimately confirms an inflammatory demyelinating lesion. Clinically some of these patients develop typical MS, while others have recurring tumefactive lesions. Acute disseminated encephalomyelitis (ADEM) is usually a monophasic disorder, often preceded by a vaccine or infection. Acute hemorrhagic leukoencephalitis (AHLE) typically presents with acute-onset fever, neck stiffness, neurological focal signs, and impaired consciousness, usually following an upper respiratory tract infection. Most authors believe that AHLE represents a hyperacute form of ADEM. Pathologically AHLE is characterized by diffuse petechial hemorrhages, ring hemorrhages surrounding necrotic venules, as well as the perivenular demyelinating lesions typical of ADEM.

Neuromyelitis optic (NMO) is characterized by either monophasic or relapsing attacks of ON and myelitis. Pathologic findings suggest a role for antibodies and local activation of complement. Recently a specific autoantibody marker was identified, named NMO-IgG, which binds at or near the blood-brain barrier (BBB) and targets aquaporin-4. This disease marker has a sensitivity and specificity of 73% and 91%, respectively^{5,6}

DIAGNOSIS

The diagnosis of MS is based on the demonstration of white-matter lesions disseminated in time and space, in the absence of another identifiable explanation. Because no single clinical feature or diagnostic test is sufficient for the diagnosis of MS, diagnostic criteria have included a combination of both clinical assessment and paraclinical studies. Newly revised diagnostic criteria were recently established by an international panel; these are now commonly known as the McDonald criteria⁷ (Table 65.1).

A diagnosis of MS can be based on clinical grounds alone if there have been two or more attacks with objective evidence of involvement of two or more areas of the CNS. If there have been two or more attacks, but

there is objective evidence of involvement of only one area of the CNS, dissemination in space must be demonstrated by additional data. If there is history of only one clinical attack or if there has been insidious neurological deterioration, additional data are needed to confirm dissemination in time and space. The paraclinical studies that can be used to prove a suspicion of MS include magnetic resonance imaging (MRI), cerebrospinal fluid (CSF) analysis, and visual evoked potentials (VEP).

By MRI, MS lesions are typically larger than 6mm, have an oval shape (often with the long axis directed perpendicular to lateral ventricles), and have preferential location in the periventricular area, corpus callosum, and posterior fossa. The typical MS lesion evolves over time and this can be followed by MRI. If caught in the initial stages, gadolinium enhancement seen on a T1-weighted image done after the administration of gadolinium contrast will correlate with a new lesion on a T2-weighted image. The contrast-enhancing lesion indicates BBB disruption. Inflammation and edema will usually persist for no longer than 2 months and in most cases less than 1 month. As edema resolves the persistent T2-weighted lesion will often become smaller and more sharply delineated from the surrounding white matter. In some instances the lesion seen on the T2-weighted image will be seen as hypointense on a T1-weighted image. The low-attenuation T1 signal or 'T1 black hole,' which often becomes more common in secondary progressive MS, is thought to represent actual tissue loss⁸ (Fig. 65.2). Disease activity assessed by MRI, defined as either the number of new, recurrent, and enlarging lesions or the number of gadolinium-enhancing lesions, is usually higher than the clinical activity. The difference may be either because of the involvement of asymptomatic areas of the CNS or because of a pathophysiological difference between symptomatic and nonsymptomatic lesions based on the presence or absence of axonal dysfunction. Because of the high sensitivity of MRI for disease activity, periodic MRI have been helpful in determining treatment efficacy more quickly than monitoring relapse rate or disability level. For this reason, MRI has become an important tool in recent clinical trials.

MRI criteria for the diagnosis of MS have been formally incorporated into the diagnostic criteria for MS^{7,9} (Tables 65.2 and (65.3). Importantly, MRI can be used to establish dissemination in either space or time. One implication of the revised diagnostic criteria is that a diagnosis of MS can potentially be made 3 months after a single clinical presentation consistent with MS (see Table 65.2). It is important to note that as with acute disease activity, there is only poor correlation between disability and lesion load (volume of white-matter abnormalities) determined by brain MRI. Severe clinical impairment with few MRI abnormalities, and the converse, occur. This disparity is partially explained by variable spinal cord involvement, but a pathophysiological difference may account for some of the discrepancy. The correlation between 'T1 black holes' and disability seems better. While other imaging techniques, including magnetization transfer ratios and MR spectroscopy, have proved to be very useful research tools, to date they do not have a role in the diagnosis of MS.

CSF evaluation remains a valuable diagnostic tool for MS. A lymphocytic pleocytosis can be seen during acute exacerbations in about one-third of patients, but this seldom exceeds 50 cells per dl. High immunoglobulin levels due to intrathecal synthesis can be seen. The majority of CSF immunoglobulin is immunoglobulin G (IgG), although IgM and IgA can also be elevated. The IgG index and synthesis rate are elevated in 70–90% of MS patients. Agarose gel electrophoresis or

KEY CONCEPTS

- >> Pathologically, multiple sclerosis is characterized by discrete inflammatory, demyelinating lesions of the white matter and gray matter, axonal degeneration, diffuse changes of 'normal-appearing white matter,' and remyelination
- >> Multiple sclerosis is a biphasic disease characterized by an early inflammatory phase followed by a progressive neurodegenerative phase

Table 65.1 Revised McDonald diagnostic criteria for multiple sclerosis (MS)

Clinical presentation	Additional data needed for multiple sclerosis diagnosis
Two or more attacks ^a ; objective clinical evidence of two or more lesions	None ^b
Two or more attacks ^a ; objective clinical evidence of one lesion	Dissemination in space, demonstrated by: MRI ^c <i>or</i> Two or more MRI-detected lesions consistent with MS plus positive CSF ^d <i>or</i>
One attack ^a ; objective clinical evidence of two or more lesions	Await further clinical attack ^a implicating a different site Dissemination in time, demonstrated by: MRI ^e <i>or</i> Second clinical attack ^a
One attack: objective clinical evidence of one lesion (monosymptomatic presentation; clinically isolated syndrome)	Dissemination in space, demonstrated by: MRI ^c <i>or</i> Two or more MRI-detected lesions consistent with MS plus positive CSF ^d <i>and</i> Dissemination in time, demonstrated by: MRI ^e <i>or</i> Second clinical attack ^a
Insidious neurological progression suggestive of MS	One year of disease progression (retrospectively or prospective determined) <i>and</i> Two or more of the following: Positive brain MRI (nine T2 lesions or four or more T2 lesions with positive VEP) Positive spinal cord MRI (two focal T2 lesions) Positive CSF ^d

CSF, cerebrospinal fluid; MRI, magnetic resonance imaging; VEP, visual evoked potential.

If criteria are fulfilled and there is no better explanation for the clinical presentation, the diagnosis is MS; if suspicious, but the criteria are not completely met, the diagnosis is 'possible MS'; if another diagnosis arises during the evaluation that explains the entire clinical presentation better, then the diagnosis is 'not MS.'

^aAn attack is defined as an episode of neurological disturbance for which causative lesions are likely to be inflammatory and demyelinating in nature. There should be subjective report (backed up by objective findings) or objective observation that the event lasts for at least 24 hours.

^bNo additional tests are required; however, if tests (MRI, CSF) are undertaken and are negative, extreme caution needs to be taken before making a diagnosis of MS. Alternative diagnoses must be considered. There must be no better explanation for the clinical picture and some objective evidence to support a diagnosis of MS.

^cMRI demonstration of space dissemination must fulfill the criteria detailed in Table 65.2.

^dPositive CSF determined by oligoclonal bands detected by established methods (isoelectric focusing) different from any such bands in serum, or by an increased immunoglobulin G index.

^eMRI demonstration of time dissemination must fulfill the criteria in Table 65.1.

Adapted from Polman CH, et al. Diagnostic criteria for multiple sclerosis: 2005 revisions to the 'McDonald criteria.' *Ann Neurol* 2005; 58: 840–846.

isoelectric focusing of CSF proteins often reveals discrete bands of immunoglobulin, each representing a monoclonal antibody. Unique banding patterns in the CSF, not present in the serum, are known as oligoclonal bands (OCBs) and are indicative of intrathecal humoral immune response. Between 85% and 95% of MS patients have OCBs; however, early in the course of disease they are not as prevalent. Once present, OCBs persist and the pattern does not vary, although new bands occasionally appear. The antigenic specificity of OCBs is unknown.¹

Evoked potentials are summed cortical electrical responses to peripheral sensory stimulation that can be used to localize sites of pathology and measure conduction velocity along sensory pathways. VEP and somatosensory evoked potentials can detect subclinical sites of demyelination, thus providing evidence of multifocality of MS lesions. Some 85% of patients with MS have abnormalities on VEPs, even when the history of ON is absent.¹

KEY CONCEPTS

- >> Multiple sclerosis is a multifactorial disease most likely due to exposure to environmental triggers in a genetically susceptible individual
- >> The inflammatory phase is thought to be driven by autoreactive CD4 T cells specific for myelin epitopes
- >> It is not clear if the neurodegenerative phase is a consequence of immune-mediated injury or has an unrelated cause

Fig. 65.2 Magnetic resonance imaging (MRI) in multiple sclerosis (MS). **(A)** T1-weighted spin echo (WSE) post contrast MRI obtained in an MS patient after the injection of a single dose (0.1 mmol/kg of body weight) of gadolinium diethylenetriamine pentacid (Gd-DTPA). Two active lesions are visible on the MRI, indicated by the arrows. Several chronic hypointense lesions (T1 'black holes') are seen surrounding the ventricles. **(B)** T2-WSE MRI showing both chronic and acute MS lesions in the same patient.

Table 65.2 Magnetic resonance imaging criteria to demonstrate dissemination of lesions in time

There are two ways to show dissemination in time using imaging:

- Detection of gadolinium enhancement at least 3 months after the onset of the initial clinical event, if not at the site corresponding to the initial event
- Detection of a new T2 lesion if it appears at any time compared with a reference scan done at least 30 days after the onset of the initial clinical event

Adapted from Polman CH, et al. Diagnostic criteria for multiple sclerosis: 2005 revisions to the 'McDonald criteria.' *Ann Neurol* 2005; 58: 840–846.

A set of criteria have also been established for the diagnosis of primary progressive MS. By definition, all patients with primary progressive MS have a slowly progressive and often monosymptomatic course, frequently consisting of spastic paraparesis without clinical signs of dissemination in the CNS. A proportion of patients may have multiple symptoms at onset.¹⁰ Just as in relapsing remitting MS, in addition to the clinical history, CSF findings, VEPs, and abnormal MRI are often helpful in making a diagnosis. In this case, exclusion of other causes of slowly progressive degenerative disease is essential¹¹ (Table 65.4).

Table 65.3 Magnetic resonance imaging criteria to demonstrate brain abnormality and demonstration of dissemination in space

Three of the following:

- At least one gadolinium-enhancing lesion or nine T2 hyperintense lesions if there is no gadolinium-enhancing lesion
- At least one infratentorial lesion
- At least one juxtacortical lesion
- At least three periventricular lesions

Note: A spinal cord lesion can be considered equivalent to a brain infratentorial lesion: an enhancing spinal cord lesion is considered to be equivalent to an enhancing brain lesion, and individual spinal cord lesions can contribute together with individual brain lesions to reach the required number of T2 lesions

Adapted from Polman CH, et al. Diagnostic criteria for multiple sclerosis: 2005 revisions to the 'McDonald criteria.' *Ann Neurol* 2005; 58: 840–846.

Table 65.4 Diagnosis of multiple sclerosis in disease with progression from onset

One year of disease progression (retrospectively or prospectively determined) *plus* two of the following:
 Positive brain magnetic resonance imaging (MRI) (nine T2 lesions or four or more T2 lesions with positive visual evoked potential)
 Positive spinal cord MRI (two focal T2 lesions)
 Positive cerebrospinal fluid (isoelectric focusing evidence of oligoclonal immunoglobulin G (IgG) bands or increased IgG index, or both)

Adapted from Polman CH, et al. Diagnostic criteria for multiple sclerosis: 2005 revisions to the 'McDonald criteria.' *Ann Neurol* 2005; 58: 840–846.

NEUROPATHOLOGY

MS is a CNS disease histopathologically characterized by discrete areas of myelin, oligodendrocyte, and axonal loss, called plaques or MS lesions. These lesions are seen in the cerebral hemispheres, the brainstem, spinal cord, optic nerves and chiasm, and the cerebellum. Although MS has long been regarded as a white-matter disease, MS lesions occur in all CNS parenchymal areas, including cerebral cortex and deep gray matter. Studies have confirmed that the extent of cortical demyelination does not correlate with the extent of focal white-matter demyelination. Extensive cortical demyelination is associated with the progressive phases of disease, while less cortical demyelination has been seen in relapsing remitting MS.

The pathological hallmarks of MS lesions are inflammatory infiltrates with T cells, B cells, and macrophages/microglia; demyelination with oligodendrocyte loss; and a variable degree of remyelination, axonal loss, and gliosis. The mechanisms of tissue damage in MS lesions are not yet fully understood. Besides the inflammatory-demyelinating component, an additional neurodegenerative component appears to be involved, leading to extensive neuroaxonal damage in the chronic MS brain. Regenerative processes such as remyelination are also present in the MS brain and may be extensive, especially early in the course of disease.

The terms active/acute, subacute or chronic active and chronic inactive are used to stage MS lesions. Active/acute lesions have traditionally been defined as showing demyelination with inflammatory infiltrates, while chronic lesions show demyelination with little or no inflammation. The subacute or chronic active lesion is one with a chronic core and active edge, or else one with a low level of inflammatory activity.¹²

The hallmark of the acute lesion is a robust inflammatory response, consisting of lymphocytes, macrophages, occasional plasma cells, or even eosinophils, which may also be scattered in chronic lesions. These form the active rim of expanding chronic active or subacute lesions. The T cells seen in MS lesions consist of both CD4 and CD8 cells.¹²

Investigators examining brain specimens from patients who have diagnostic brain biopsies or from patients with MS who have died have resulted in the description of four pathological patterns.⁵ Pattern 1 (macrophage-associated demyelination), representing 15% of lesions, shows inflammatory demyelination marked by macrophage infiltration. The most common is Pattern 2 (antibody-associated demyelination) found in 58% of lesions,

which demonstrates well-demarcated zones of demyelination and striking T-cell inflammation. With the use of specific stains it can be shown that all myelin proteins are lost simultaneously. This lesion is characterized by the striking deposition of complement, especially C9neo component, around blood vessels and on myelin. On MRI, the edges of these lesions show gadolinium enhancement, indicative of BBB breakdown. Oligodendrocytes are relatively well preserved, and remyelination is frequently found.

In Pattern 3, the next most common lesion type at 26%, demyelination and inflammation occur. However the plaque is less sharply delineated. These lesions are characterized by oligodendrocyte apoptosis, marked reduction in oligodendrocytes, and minimal remyelination. In this pattern, there is selective loss of myelin-associated glycoprotein (MAG) compared with the other myelin proteins, which is suggestive of a lesion at the level of the oligodendroglial cell body. For this reason, this pattern has been termed a distal oligodendroglialopathy. In these cases, Balo-like rings are often found and on MRI there tends to be little gadolinium enhancement.^{6,12}

Pattern 4 (primary oligodendrocyte degeneration) is a rare form that shows nonapoptotic oligodendrocyte death in the normal-appearing adjacent periplaque white matter. The demographic and clinical features of these patients, however, are indistinguishable from those of typical MS patients.^{6,12}

These various patterns of demyelination have suggested the existence of multiple etiologies and pathogenesis between patients and point to the possibility of MS as a heterogeneous disease. Supporting lesion heterogeneity is the observation of differential expression of chemokine receptors on monocytes/macrophages in actively demyelinating lesions.¹³ The pathological heterogeneity of the MS lesion remains an area of active research.

Recent pathological studies on a limited number of patients, conducted on tissue just hours after the onset of disease exacerbation, noted the presence of lesions characterized by areas with apoptotic oligodendrocytes and macrophage activity with a paucity of inflammatory cells. These lesions have been termed early apoptotic oligodendrocyte lesions, and it has been postulated that all MS lesions may start this way. An ischemic or metabolic insult to the oligodendrocyte is hypothesized to be the initiating event, and presumably inflammatory changes would be secondary events due to the oligodendrocyte injury.^{14,15} These findings are not, however, substantially different from those found in pattern 3 described above, where a similar anoxic/toxic insult is suggested.

Previously unrecognized diffuse white-matter involvement in the areas that appear grossly normal has been clearly demonstrated by sophisticated forms of MR examination, including reduced magnetization transfer ratios, changes in diffusion coefficient, and decreased *N*-acetyl aspartic acid (neuronal marker) by MR spectroscopy. Pathological examination of these areas has shown active demyelination, with macrophages filled with myelin components in varying stages of degradation, diffuse, mainly CD8⁺ T-cell infiltrates, microglial activation, diffuse axonal injury with axonal spheroids, gliosis, and even some remyelination.^{6,12} It is unclear if these represent lesions in their first stages of development or secondary Wallerian degeneration, serial imaging studies have shown subsequent typical plaque formation in the same areas highlighted by these imaging methods.¹²

Significant destruction of axons in MS has been recognized from the time of the earliest pathological descriptions, but the degree of axonal damage and the presence of axonal destruction in the acute MS lesion

have only recently been characterized. Axonal degeneration correlates with the presence of permanent black holes on T1-weighted MRI and the extent of atrophy in the spinal cord. Because these imaging parameters correlate with clinical disability, axonal damage is likely responsible for irreversible clinical disability in MS. This is one of the striking pathological features of progressive MS. The extent of axonal transection in early active lesions correlates with inflammation; the magnitude of axonal loss in chronic lesions suggests that mechanisms other than inflammatory demyelination may contribute to axonal damage at later stages. A slow subclinical inflammatory process has been suggested, continuing throughout the disease course and not causing clinical relapses or gadolinium enhancement (the standard markers of acute inflammation). However, other possibilities include loss of trophic factors from oligodendrocytes and myelin, loss of a physical barrier protecting the axon from exposure to destructive factors, or rearrangement of Na⁺ and K⁺ channels on demyelinated axons that may place an undue metabolic stress on the axons.¹²

The CNS is capable of remyelination, and this occurs commonly in MS. The extent of remyelination in MS varies, with up to 28% of plaques being remyelinated. Efficient remyelination requires the presence of undamaged axons and a sufficient number of residual oligodendrocytes or oligodendrocyte precursors. Areas of extensive remyelination in correspondence with acute and early MS plaques are referred to as 'shadow plaques'.⁶

A unique pathological finding is Balo's concentric sclerosis, which was originally described as a distinct disease entity. Pathologically it consists of ring-shaped lesions composed of alternating bands of demyelination and normally preserved myelin. Similar tigroid lesions are found in MS. The demyelinated bands contain high levels of inducible nitric oxide synthetase, a mediator of inflammatory damage, while preserved myelin contains high levels of proteins involved in hypoxic preconditioning, such as hypoxia-inducing factor (HIF), heat shock protein 70 (HSP-70), and D-110 molecules. These observations suggest that hypoxia may play an important role in mediating tissue injury and contributing to the concentricity typical of this pattern of demyelination. Because of the neuroprotective effects of HIF and HSP-70, it has been hypothesized that the inflammatory process induces hypoxic stress in the periphery of the lesion, the preserved band, rendering this area more resistant to subsequent ischemic assaults. This is consistent with the presence of Balo-like changes in the pattern 3 MS lesions, in which a possible hypoxic etiology has been postulated.¹²

Few pathological studies have focused on patients with primary or secondary progressive MS. The most relevant findings in these reports are the presence of slowly expanding plaques with foamy macrophages containing lipids, especially in periplaque white matter. The description of absent or modest perivascular cuffs in the lesions, but the presence of lymphocytes and plasma cells in the periplaque white matter, is consistent with reduced inflammatory activity. Recently, demyelination in the cerebral cortex, diffuse injury in the form of focal axonal swelling and axonal spheroids, and diffuse rather than focal inflammation (defined as diffuse T-cell infiltration and microglial activation) were shown to be significantly increased in primary progressive and secondary progressive compared to relapsing remitting MS. Results of these studies seem to indicate that inflammation remains an important aspect of pathological changes in secondary progressive MS, albeit with different patterns than in the relapsing remitting MS.⁴

Fig. 65.3 Multiple sclerosis (MS) disease phases. MS disease course over time is characterized by progressive reduction in inflammation and progressive prevalence of neurodegenerative features. This is reflected in the decrease of clinical relapses over time with accumulation of disability (A), the accumulation of T2 lesion load by MRI (B), the decrease of contrast-enhancing lesions (vertical lines), and the irreversible loss of myelin and axons with progressive brain atrophy and decline in brain volume (C).

Most authors now consider MS a biphasic disease, with an early inflammatory period and a subsequent degenerative process, characterized by a progression to brain and spinal cord atrophy in the absence of overt relapses and significant inflammation (Fig. 65.3). Two observational studies of MS natural history found that the progression of disability is not affected by relapses, either those before the onset of the progressive phase or those that occur during this phase. However, the rate of cerebral atrophy is greatest in patients with the highest inflammatory lesion burden before treatment, suggesting these two features are not entirely independent.¹⁶ The answer as to how progression and episodic disease activity are related will be demonstrated by effectiveness of early treatment in eliminating new episodes and accumulation of disability and onset of progression.

PATHOGENESIS

The long-favored hypothesis in MS implicates autoreactive T cells against myelin components, generated in the periphery, that access the CNS where they persist and induce an inflammatory cascade that results in the injury of previously normal neural tissues. Data in the animal model experimental autoimmune encephalomyelitis (EAE), that is initiated by systemic immunization with neuronal autoantigens, or by transfer of CD4 T cells sensitized with neuronal antigen, have provided support for an autoimmune process in MS.

Considerable evidence now exists for an immunological basis of the acute MS lesion. Various forms of immunosuppression and/or immunomodulation can substantially alter both the frequency of relapses as

well as the frequency of contrast-enhancing lesions on MRI. However, most of these therapies have failed to produce a substantial effect on the progression of disability. The discrepancy has led some to argue that MS is primarily a degenerative disease with the immune component occurring as a secondary process. Since immunomodulation does have a modest effect on progression when used early in the disease, it seems likely that immunopathology is essential for the initial stages of the disease. Less clear is the cause of the more diffuse degenerative process that is now recognized. It is not clear if the damage seen in axons in the white matter and gray matter is a direct result of the immunopathology, is secondary to damage occurring at the time of the acute lesion, or has a completely unrelated cause. Most likely the damage caused by the acute, inflammatory process sets the stage for a subsequent degenerative process. Clearly MS is a complex, multifactorial disease in which genetic, nongenetic, and immunological aspects need to be considered.

NONGENETIC FACTORS

The relatively low concordance rate of identical twins indicates a contribution of nongenetic factors to MS etiology. Both infectious agents and behavioral or lifestyle influences have been proposed to induce or contribute to disease expression.

Different lines of evidence point to the role of environmental contributions. A north-south gradient in disease prevalence on the northern hemisphere and the opposite on the southern hemisphere, which cannot be explained by genetic factors alone, has been repeatedly documented. Migration studies have shown that individuals migrating from areas of high prevalence of MS to areas of low prevalence before the age of 15–16 acquire low risk of MS development, whereas migration after 15–16 does not change the risk. These epidemiological data support exposure to environmental factors in childhood as important in determining risk of disease development. Infections are the favored interpretation of this data; however dietary fatty acids and vitamin D levels have recently received attention. In addition, other factors such as ultraviolet radiation exposure, organic solvent exposure, and cigarette smoking have also been invoked.¹⁷

Viral and bacterial infections are logical candidates as environmental triggers of MS. Of interest, EAE studies show that almost 100% of transgenic mice expressing a T-cell receptor (TCR) that is specific for an encephalitogenic peptide of myelin basic protein (MBP) develop EAE when they are housed under nonpathogen-free conditions, whereas the same animals housed in a specific-pathogen-free facility remain disease-free. While reports of associations between infections are extensive, no single infectious agent has been detected reproducibly. Current data suggest that MS could be induced or exacerbated by many different microbial infections, and the responsible agents are most likely ubiquitous pathogens that are highly prevalent in the general population.

Viruses that induce persistent infections, such as herpes or retroviruses, have been studied extensively in MS. Herpes viruses are of particular interest due to their neurotropism, ubiquitous nature, and tendency to produce latent, recurrent infections. Among these, human herpes virus 6 (HHV-6) and Epstein-Barr virus (EBV) are leading candidates. The seroprevalence in the general population for both is high. Observations suggest that HHV-6 may play a role in MS, including its detection in oligodendrocytes in MS plaque tissue (but also in normal brain), infection of astrocytes, and the presence of HHV-6 DNA and anti-HHV-6

KEY CONCEPTS

- >> Treatment of multiple sclerosis includes management of acute exacerbations, disease-modifying therapies, and symptomatic treatment
- >> Approved disease-modifying therapies for relapsing-remitting multiple sclerosis include interferon- β , glatiramer acetate, mitoxantrone, and natalizumab

IgG and IgM antibodies in the serum and CSF of MS patients. DNA and serological data, however, are controversial; the existence of two different HHV-6 variants may account for some of the discrepancies. EBV has also been linked with MS. Anti-EBV antibodies are elevated in patients with MS (seropositivity is 100% versus 90% in the general population) and MS patients reactivate latent EBV infections more often, correlating with relapses.^{17,18}

Molecular mimicry and bystander activation, or a combination of these, are the main mechanisms used to explain how infections could induce MS. The recognition of self-antigens at intermediate levels of affinity by T cells during thymic maturation leads to positive selection and export of these T cells to the periphery. Cross-reactivity of these potentially self-reactive T cells with foreign antigens (molecular mimicry) can lead to activation during infection. Previously immune reactivity was thought to be strictly specific and complete sequence homology was thought to be necessary for molecular mimicry to occur. It is now clear that cross-reactivity can occur with peptides that share no amino acids in their sequence and that each amino acid in a peptide contributes independently and additively to recognition by the TCR.¹⁹ This suggests that molecular mimicry could occur more frequently than previously expected. Despite this, there is little evidence that molecular mimicry occurs in human autoimmune disease.

Bystander activation refers to a mechanism by which autoreactive T cells are activated as a consequence of nonspecific inflammatory events during infections. Cytokines, superantigens, and infectious-derived, proinflammatory agents such as lipopolysaccharide are capable of activating autoreactive T cells.¹⁷

HLA AND GENETICS

Familial aggregation has long been noted in MS. First-, second-, and third-degree relatives of people with MS have a greater risk of developing MS than the general population; this risk varies with degree of relatedness, with MS being 20–40 times more common in first-degree relatives, and dropping off rapidly thereafter. Adoption studies have shown that adoptive relatives, although raised from infancy with the MS patient, were no more likely to develop MS than expected for the general population, suggesting that familial aggregation is due to genetic sharing rather than shared family environment. Half-sibling studies support this data. Twin studies have shown there is an excess of monozygotic concordance (25–30%) compared with dizygotic concordance (3–5%).²⁰

As in other T-cell-mediated autoimmune diseases, human leukocyte antigen (HLA)-DR and -DQ molecules are by far the strongest genetic risk factors in MS. In Caucasians, the specific genes that confer risk are

the HLA-DR15 haplotype (DRB1*1501, DRB5*0101, DQA1*0102, DQB1*0602). A dose effect in DR15 homozygotic MS patients has also been described. Links with other DR molecules in ethnically more distant populations have been described.^{17,18} The association of MS with HLA class I alleles appears to be much lower. However, HLA-A3 and -B7 are overrepresented in MS patients, and HLA-A201 has shown protective effects.¹⁷ Recently, compelling evidence has been reported that polymorphisms in IL7R, which encodes the interleukin 7 receptor alpha chain, contribute to the non-HLA genetic risk in multiple sclerosis.^{41,42}

Two other promising candidate genes have emerged. Polymorphisms of the cytokine interferon- γ (IFN- γ) and the haplotypes formed between them are associated with MS susceptibility. This has not, however, been confirmed in all tested populations. Apolipoprotein E (APOE) genotype has been associated with MS disease severity, although consensus here too is lacking. APOE3 and e4 have been associated with neuronal loss, APOE2 is associated with less severe disease in women, and APOE4 has been associated with progressive disease in women and cognitive impairment in men with MS. These associations further suggest the presence of genetic contributions to MS etiology and phenotype.²¹

IMMUNOLOGY

The activation of autoreactive CD4 T cells in the periphery is considered to be the first important immunological event in MS. This is supported by data obtained from the animal model EAE, which is initiated by systemic immunization with neuronal autoantigens or by transfer of CD4 T cells sensitized with neuronal antigen. Transfer of antibodies alone or of activated monocytes does not result in disease, and myelin-specific CD8 T cells induce EAE only under special circumstances. An increased frequency of CD4 myelin-reactive T cells in the peripheral blood of MS patients compared with healthy donors, seemingly derived from the memory T-cell pool, implicates prior sensitization with disease-relevant antigens.²² Such clones have been shown to exist in the peripheral blood for long periods of time and may be reactivated during disease exacerbation. Interestingly, it appears that regulation of CD4 T-cell apoptosis is perturbed in MS, with increased expression of anti-apoptotic molecules, that is further heightened during disease exacerbation and downregulation by IFN- β . Myelin-specific T cells in MS are relatively skewed toward a Th1 proinflammatory phenotype. Fluctuations of cytokine secretion have been linked to MRI-documented inflammatory activity: elevated expression of the proinflammatory cytokines IFN- γ and tumor necrosis factor- α (TNF- α) have correlated with disease activity, while IL-10 has shown relatively higher levels during remissions. All these data, as well as the association of MS with distinct HLA class II molecules, support a central role for CD4 T cells in the pathogenesis of MS.¹⁷

The activation of CD4 T cells is thought to occur following exposure to environmental influences, the favored trigger being infectious agents. This could lead to activation through molecular mimicry, bystander activation, or a combination of these. Alterations in the activation thresholds of autoreactive CD4 T cells due to abnormal requirements for co-stimulation probably play a role. CD4 myelin-specific T cells, as well as T cells with specificity for other antigens, are either less dependent or independent of co-stimulation.²³ In addition, the number and function of CD4⁺CD25⁺ immunoregulatory T cells (Tregs) appear reduced in MS patients. CD4 Tregs, characterized by CD25^{high} expression and expression

of the transcription factor FOX-P3, suppress T-cell proliferation by both cell-cell contact and cytokine-mediated mechanisms.²⁴ The alteration of this population of regulatory cells could facilitate the activation of autoreactive CD4 T cells in the periphery.

Recent evidence suggests that the innate immune system may also be involved in immune regulation. Natural killer (NK) cells have reduced activity in MS, and their function appears to fluctuate in relation to disease exacerbations.²⁵ Of interest are the results from a recent phase II clinical trial with daclizumab, a humanized monoclonal antibody against the IL-2 receptor α -chain, in which an expansion of the NK population associated with increased function was seen to correlate strongly with a reduction of inflammatory activity in the brains of treated patients.^{17,26}

Activated autoreactive T cells adhere to the BBB endothelium via adhesion molecules (LFA-1 and VLA-4), and transmigrate into the brain parenchyma through cerebrovascular endothelial cells. Proinflammatory cytokines (IFN- γ and TNF- α) produced by these cells activate adhesion molecules (ICAM-1, VCAM-1, and E-selectin) on the BBB. Activated CD4 T cells also produce proteolytic enzymes (MMP-2 and MMP-9) that facilitate passage through the subendothelial basement membrane.^{17,27} Thus, access to the CNS permits interaction of autoreactive T cells with the target antigen/s.

MBP is the best-studied myelin protein in MS. It is the second most abundant myelin protein (approximately 30–40%) after proteolipid protein (PLP). The highly basic MBP is positioned at the intracellular surface of myelin membranes, and via interactions with acidic lipid moieties is involved in maintaining the structure of compact myelin. MBP induces EAE in numerous mouse and rat strains, guinea pigs, and non-human primates. In humanized transgenic mouse models carrying MBP-specific TCRs from MS patients, EAE could be readily induced. In one of these models, about 4% of the animals developed spontaneous disease, clearly showing that MS patient-derived MBP-specific T cells have encephalitogenic potential.^{28,29}

PLP is the most abundant CNS myelin protein (about 50%). When comparing PLP and MBP, the former is a stronger and dominant encephalitogen in some EAE models. Upon EAE induction with whole spinal cord homogenate, the dominant T-cell response is directed against PLP.³⁰ PLP TCR transgenic mice on SJL/J background develop spontaneous EAE with high frequency.³¹

Myelin oligodendrocyte glycoprotein (MOG), a transmembrane glycoprotein of the Ig superfamily, is much less abundant than the major myelin proteins (0.01–0.05%), and it is not located in compact myelin but rather on the outer surface of the oligodendrocyte membrane. Owing to this location, it is directly accessible to antibodies and therefore an easy target for both cellular and humoral immune responses in MS. Of interest, a MOG-TCR transgenic mouse model demonstrates spontaneous EAE in only a small fraction of animals, while 35% develop spontaneous ON.³²

Other candidate antigens which have been studied include MAG, 2',3'-cyclic nucleotide 3' phosphodiesterase (CNPase), myelin-associated oligodendrocytic basic protein (MOBP), oligodendrocyte-specific glycoprotein (OSP), alpha-b crystalline, S100 β protein, transaldolase-H, and lipid components.¹⁷

Destruction of CNS tissue during autoimmune inflammation leads to release of self-antigens, which can then be processed and presented by antigen-presenting cells, resulting in the *de novo* activation of autoreactive T cells. This cascade of events can also lead to epitope spreading, in which the initial epitope-specific T-cell response broadens to include

other epitopes on the same molecule and on different antigens. This process probably plays an important role in the progression and perpetuation of the autoimmune response.

Upon local reactivation, proinflammatory cytokines (IFN- γ , IL-23, TNF- α , lymphotoxin) and chemokines released by the CD4 T cells activate resident cells, such as microglia and astrocytes, recruit other immune cells, including monocytes, CD8 T cells, B cells, and mast cells from the peripheral blood, and contribute to the formation of the inflammatory lesion. A significant number of chemokines and the corresponding receptors have been detected in MS brain lesions, supporting a pathogenic role in MS. These include CCL3 (MIP-1a), CCL4 (MIP-1b), and CCL5 (RANTES), CCL2 (MCP-1), CCL7 (MCP-3), CCL8 (MCP-2), and CXCL10 (IP-10), all of which have also been found in active MS lesions.^{17,27}

Ultimately numerous processes contribute to myelin/oligodendrocyte and axonal damage, including free radicals, cytokines, direct complement deposition, antibody-mediated complement activation and antibody-dependent cellular cytotoxicity via Fc-receptors, myelin phagocytosis, direct lysis of axons by CD8 cytotoxic T lymphocytes, the secretion of proteases, lysis of oligodendrocytes by $\gamma\delta$ T cells, and apoptosis of oligodendrocytes.

Only a low level of B cells (< 1%) are able to cross the intact BBB; however, once inflammation disrupts the BBB, B cells, antibodies, and complement can enter the CNS. B cells, plasma cells, and myelin-specific antibodies are detected in MS plaques and in areas of active demyelination in MS patients. The observation of increased immunoglobulins in the CSF in MS patients, but not in the serum, indicates intrathecal production. These CSF Igs are typically oligoclonal, although their specificity is unknown. Within the CNS, B cells can serve as antigen-presenting cells and can provide co-stimulatory signals to autoreactive T cells, thereby contributing to inflammatory process. B cells and tissue-bound Ig can recruit further autoreactive T cells to the CNS. Furthermore, the activation of idiotope-specific T cells by CSF Igs has been described. The production of myelin-specific antibodies and the destruction of myelin within plaques are probably the most significant contributions of B cells to MS pathogenesis.^{17,33}

Different lines of evidence suggest contribution by CD8 T cells in pathogenesis. Except for microglia, none of the resident CNS cells express MHC class II constitutively including oligodendrocytes and neurons, however they can be recognized by CD8 T cells. Clonally expanded CD8 memory T cells have been found in the CSF and in MS brain tissue, and a persistence of CD8 T-cell clones is seen in CSF and blood. In the MS lesion, CD8 T cells predominate. HLA class I-restricted myelin epitopes have been described and the CD8 cytotoxic T-cell response to MBP is increased in MS patients. In addition, histological evidence suggests CD8 T cells may act as effector cells in axonal loss, with an increased frequency of CD8 T cells significantly correlating with the presence of increased amyloid precursor protein (APP), a marker of axonal damage, within neuronal axons.^{17,34}

In addition to these mechanisms of injury, evidence suggests that denuded axons are especially vulnerable to the inflammatory environment of acute lesions. The release of excessive quantities of glutamate by macrophages can cause excitotoxicity and death of neurons and oligodendrocytes. Markers for glutamate production and glutamate receptors are upregulated in MS lesions and appear to correlate with disease severity and axonal damage.²⁷

The inflammatory event lasts from a few days to 2 weeks. The natural resolution of the inflammatory process may be explained in part by the function of the subpopulation of regulatory T cells, as well as by activated

NK cells that have been shown to have suppressive effects of antigen-specific Th1 responses and to favor Th2 function.²⁷ The result is characterized by stretches of denuded axons, apoptotic oligodendrocytes and T cells, axon transections, macrophages loaded with phagocytosed myelin lipids, and the activation and proliferation of astrocytes. Besides clearing debris, further lesion resolution includes a relative dominance of Th2/Th3 cytokines, such as IL-10 and transforming growth factor- β , and the secretion of various growth factors (brain-derived neurotrophic factor, platelet-derived growth factor, ciliary neurotropy factor, and fibroblast growth factors) by both resident cells and T cells. Oligodendrocyte precursors that are still present in the adult CNS are also activated, and surviving oligodendrocytes begin to remyelinate denuded internode areas. The original thickness of the compact myelin is not reached again and therefore nerve conduction velocity remains slower in these regions.¹⁷ Myelin debris contains several inhibitory molecules, including Nogo-A, MAG, and OMgp, all of which are physiologically relevant during maturation of the CNS and can impede the repair process.

It appears that the failure of adequate remyelination is the result of an inhospitable environment within the plaque or lack of sufficient signals for extensive myelination rather than a lack of myelin precursor cells.¹⁸ During the months and years following an inflammatory event, the cellular composition of the lesion changes dramatically. Chronic plaques can show smoldering inflammation, but are often devoid of inflammatory cells and characterized by loss of myelin and axons, relative increases in astrocytes and gliosis.

TREATMENT

During the past decade, the advent of disease-modifying treatments has substantially changed the approach to relapsing remitting MS. Early treatment initiation is now recommended to maximize the efficacy of currently available therapies that are known to act mainly against the inflammatory components of MS. By contrast, the understanding and treatment of the progressive phase of MS, which is characterized by the steady accumulation of fixed disability, are suboptimal.

Treatment of acute exacerbations of disease and disease-modifying therapy are considered below. Most patients with MS are also managed with symptomatic treatment directed at specific issues, such as bladder dysfunction, paresthesias, pain, spasticity, depression, and fatigue. Moreover, many patients benefit from physical therapy and occupational therapy, and the use of assistive devices such as ankle-foot orthotics, canes, or walkers. These strategies are essential for the global care of MS patients.

Corticosteroids are the most commonly used treatment for acute exacerbations of MS, although there have been few studies to address their efficacy. The current recommendation is to treat disabling attacks with 500–1000 mg of intravenous methylprednisolone per day for 3–5 days with or without a short tapering dose of oral corticosteroids. Evidence suggests that intravenous steroids may also have long-term effects on disease progression when given at regular intervals. Up to one-third of patients do not have adequate recovery after relapse despite use of corticosteroids. Plasma exchange was found to be beneficial in a substantial proportion of patients with severe inflammatory demyelinating episodes who had failed treatment with intravenous methylprednisolone.³⁵

Several drugs have been approved as disease-modifying agents in the treatment of MS. The treatment of different phases of the disease must be considered separately as the recommendations are different.^{36,37}

For the treatment of clinically definite MS, different options are available. IFN- β are a class of peptides that have antiviral and immunoregulatory functions. IFN- β_{1b} was the first drug approved by the US Food and Drug Administration specifically for the treatment of MS. A large clinical study in relapsing remitting MS demonstrated a reduction in the frequency of relapses by about one-third. The severity of the relapses was also lessened and there was a striking effect on MRI measures of disease activity. No difference was found in disability levels however. IFN- β_{1a} has the same amino acid sequence as natural IFN- β and differs from IFN- β_{1b} by one amino acid and by the presence of carbohydrate moieties. This drug was found to have effects similar to that of IFN- β_{1b} in reducing the frequency of MS relapses and in addition seems to have a favorable effect on disability. IFN- β has been shown to upregulate and increase the shedding of adhesion molecules, induce IL-10, and neurotrophic factors, block the opening of the BBB via inhibition of MMP-2 and -9, and reduce cell adhesion to the BBB.

Glatiramer acetate (GA) is a synthetic mixture of polypeptides produced by the random combination of four amino acids that are frequent in MBP. This drug has demonstrated a 29% reduction in relapse rate. GA reduces new lesion formation, the number of T2-enhancing lesions, lesion volumes, and the percentage of new lesions that will evolve into black holes, although the MRI effect is not apparent until the agent has been used for at least 6 months. The effect of GA that is probably most important is the induction of a relative skewing towards Th2 reactivity. GA has also been shown to displace autoantigenic peptides from HLA class II binding grooves; induce polyclonal T cell activation; act as a partial agonist, induce Th2 activation and cross-reactivity with myelin

peptides; shift the antibody response toward IgG₄; interfere with dendritic cell differentiation; and induce brain-derived neurotrophic factors.

Natalizumab is a humanized monoclonal antibody directed against the α_4 -subunit of $\alpha_4\beta_1$ -integrin, a cellular adhesion molecule (CAM) that is expressed on the surface of leukocytes and binds to vascular CAM1 (VCAM1) on the surface of endothelial cells of the brain and spinal cord. Such binding allows the leukocytes to cross the BBB into the CNS, and blockage of this interaction prevents this influx. Two trials conducted to date on the use of natalizumab alone or in combination with IFN- β_{1a} showed that this drug is more effective than other available drugs, with a decrease in relapse rate by 60% and disability progression by 40% over a 2-year period. Concerns about safety have been raised because of an increased incidence of progressive multifocal leukoencephalopathy. This risk appears to be increased if patients are on concurrent immunosuppressive treatment.³⁸

Mitoxantrone is a cytotoxic anthracedione with potent immunosuppressive activity. This drug has been approved for worsening relapsing remitting MS, secondary progressive MS, and progressive relapsing MS. The major toxicity of mitoxantrone is cardiac, and a cumulative dose-related cardiotoxicity limits lifetime exposure.

Several off-label therapies are used in the treatment of MS, including cyclophosphamide, azathioprine, methotrexate, cladribine, cyclosporine, and intravenous immunoglobulin.^{1,39}

Some disagreement exists regarding when treatment should be implemented, in part reflected in regional differences in reimbursement for therapy. Evidence supports the use of IFN- β in early treatment in patients presenting with a first attack of presumed MS (CIS), with a

Table 65.5 Multiple sclerosis therapies under investigation

Therapy	Proposed mechanism	Disease phase
HMG-CoA reductase inhibitors (statins)	Immunomodulatory actions Reduces inflammatory mediators	Active disease
Daclizumab (zenapax)	Enhances immunoregulatory mechanisms	Active disease
FTY720 (sphingosine 1-phosphatase receptor agonist) (fingolimod)	Sequesters T cells in lymphoid organs	Active disease
Rituximab (antiCD20)	Depletes B cells	Uncertain. May be found to be effective in limiting tissue damage
Terifluramide (dihydro-orotate dehydrogenase inhibitor)	Immunomodulatory	Active disease
Alemtuzumab (Campath) (antiCD52)	T-cell-depleting	Active disease
BG00012 (fumaric acid)	Immunomodulatory	Active disease
Minocycline	Anti-inflammatory inhibition of microglial activation	Uncertain. Possible neuroprotective effect
Mycophenolate mofetil (Cellcept)	Immunosuppression	Active disease
Hematopoietic stem cell transplant	Immunosuppression	Active disease
Estrogen derivatives	Immunoregulation	Active disease
Laquinimod	Immunomodulation	Active disease

reduced conversion to clinically definite MS. There is, however, concern for initiating chronic, aggressive treatment of patients who might not have gone on to develop progressive disease. The recently developed diagnostic criteria for MS based on MRI permit a reasonable prediction of disease course over brief time periods (3 months), even when patients have presented only one clinical episode. This allows one to partially reconcile the push toward early treatment with the need for diagnostic certainty.

On the other end of the spectrum, after approximately 15 years from the onset of disease, almost 60% of relapsing remitting MS patients enter the secondary progressive phase of the disease. The treatment of this phase has been less satisfactory. A detailed analysis of two trials of IFN- β_{1b} in secondary progressive MS provided insight into this issue. These trials showed conflicting results of the effect of this drug on disease progression. A comparison revealed baseline differences in the populations studied, with one trial having patients with shorter disease duration and continued relapses and the other having patients with longer disease duration and less relapses, likely accounted for the discrepancy. The results of these trials indicate the mechanisms underlying disease progression probably differ in different stages of the disease. The presence of continued inflammatory activity, as suggested by continued disease relapses and contrast-enhancing lesions by MRI, may characterize a population of patients who could continue to benefit from immunomodulatory therapy, such as IFN. In contrast, IFN appears to be ineffective in modifying the progression of disability related to ongoing destruction independent of, or remote to, the acute inflammatory component of the illness.⁴⁰ Similar considerations must be made for other therapies targeting immune mechanisms, such as mitoxantrone. To date, there are no approved therapies for the treatment of primary progressive MS. Currently numerous molecules in various stages of development are being studied in clinical trials. A summary is shown in Table 65.5.

SUMMARY

Over the past two decades significant progress has been made in understanding the immune mechanisms underlying MS. Several approved therapies are now available, albeit with only moderate impact on disease course. As the understanding of the pathogenesis of MS improves, newer, more targeted therapies will likely emerge. Clarifying the nature of the clinical and pathological heterogeneity, elucidating the neurodegenerative aspects and the dynamic interplay with immune mechanisms are a main focus of current research. This is expected to lead to new treatment strategies in neuroprotection and regeneration that will likely be used in combination with immunomodulatory therapies, and possibly be tailored to individuals, thereby opening a new era in the management of this disease.

Autoimmune peripheral neuropathies

Marinos C. Dalakas

66

Autoimmune peripheral neuropathies (APN) occur when immunologic tolerance to peripheral nerve components (myelin, Schwann cell, axon, and motor or ganglionic neurons) is lost. In some of these neuropathies there is direct evidence for autoimmune reactivity mediated by specific antibodies or autoreactive T lymphocytes against peripheral nerve. In others, the underlying immune-mediated mechanism is secondary or indirect, and an autoimmune cause is suspected when the neuropathy coexists with another systemic autoimmune disease or viral infection.

This chapter reviews the most common autoimmune neuropathies (Table 66.1), their clinical features and diagnostic criteria, the prevailing autoimmune phenomena that govern each neuropathy, and the most effective therapeutic approach.

■ ACUTE INFLAMMATORY POLYNEUROPATHY: THE GUILLAIN-BARRÉ SYNDROME(S) ■

Guillain-Barré syndrome (GBS) is an acute demyelinating polyneuropathy characterized by acute (within 1 week) or subacute (within 4 weeks) ascending motor weakness, areflexia, and mild or moderate sensory abnormalities.^{1, 2} It is a disease of all ages and occurs sporadically, although occasional outbreaks have been noted. In typical cases the maximum deficit is reached by the fourth week, a sign that is conventionally used to separate GBS from chronic inflammatory demyelinating polyneuropathy (CIDP), in which the disease begins slowly and progresses over several months, as discussed later. Rare patients who progress beyond the fourth week but not more than the eighth week are better classified as having an intermediate form. The intermediate form is probably a variant of both GBS and CIDP and a link between the two. Although these criteria are somewhat arbitrary, they are clinically helpful in determining prognosis and making therapeutic decisions in the early phase of the illness.

GBS is not one syndrome as initially thought, but several syndromes reflecting the varying degree of involvement of the motor or sensory

nerve fibers and the myelin sheath or the axon. The GBS syndromes or variants that we recognize today include:

- *Acute inflammatory demyelinating polyneuropathy (AIDP)*, the most common form, accounting for the majority of patients with GBS. In patients with AIDP, the acute onset of weakness may be limited to one or two limbs or to cranial nerves.² In classic cases the weakness is ascending and symmetric, starting from the legs and spreading up to the arms, the intercostal and diaphragmatic muscles, and the facial or bulbar muscles, causing dysphagia and dysarthria. Patients with acute GBS need to be monitored very carefully for impending respiratory failure, hence the need for early admission to intensive care units (ICUs). Autonomic dysfunction of varying degree occurs in up to 65% of patients; it is due to deficiency or overactivity of the sympathetic and parasympathetic nervous system.² If severe, autonomic dysregulation can be associated with sudden death due to cardiac arrhythmias, or with various hemodynamic changes such as hypertension, orthostatic hypotension, and reduced peripheral vascular tone. In GBS, the onset phase has been arbitrarily defined as lasting up to 4 weeks. Distinction between subacute cases of CIDP in which the onset phase lasts up to 8 weeks may be made only retrospectively.²
- *Acute, motor axonal neuropathy (AMAN)* is often associated with *Campylobacter jejuni* infection and GM1 antibodies, as discussed later. The primary axonal damage in this variant is due either to massive acute demyelination and inflammation, as occurs in experimental allergic neuritis when the animals are immunized with a high dose of myelin antigen,³ or to a primary axonal event mediated by macrophages without associated demyelination. The most striking features in these patients are the fulminant clinical course with severe paralysis, complete electrical inexcitability of motor nerves as early as 3–5 days after onset, and generally incomplete recovery of motor function.³ Infection with *Campylobacter jejuni* appears to be responsible for the majority of these cases.² In AMAN there is nodal and periaxonal deposition of immunoglobulin and complement, whereas macrophages invade the periaxonal space. This is in contrast to the classic demyelinating GBS (AIDP) in which immunoglobulin deposits and macrophages are noticeable at the abaxonal side of the myelin sheath.

Table 66.1 Common autoimmune neuropathies

Guillain-Barré syndrome(s)
Chronic inflammatory demyelinating polyneuropathy (CIDP) and its variants
Polyneuropathy associated with paraproteinemias
Polyneuropathies with IgM monoclonal gammopathies
IgG and IgA monoclonal gammopathy
Polyneuropathy, organomegaly, endocrinopathy, myeloma, and skin changes (POEMS) syndrome
Cryoglobulinemic polyneuropathy
Multifocal motor neuropathy with conduction block
Paraneoplastic neuropathies associated with anti-Hu antibodies
Autoimmune autonomic neuropathies
Vasculitic neuropathies
Infectious neuropathies (HIV, CMV, EBV, herpes, Lyme, leprosy, Chagas' disease, diphtheria, others)

- *Acute motor-sensory axonal neuropathy (AMSAN)*, which is like AMAN but with involvement of the sensory axons. AMSAN is histologically characterized by a large number of macrophages invading the axonal membrane of motor and sensory nerves.
- *C. Miller-Fisher syndrome*, which is characterized by acute onset of ophthalmoplegia, gait ataxia, and areflexia. The ataxia can occur in a setting of normal sensation, although 50% of patients complain of tingling paresthesias.² Muscle weakness may be absent at onset in two-thirds of cases, but in approximately a third of all patients weakness leading to paralysis with pharyngeal, facial, trunk, and respiratory muscle involvement can occur.² Nerve conduction studies are consistent with proximal demyelination. The C. Miller-Fisher syndrome is a distinct variant, as supported by the presence of a unique IgG antibody against GQ1b ganglioside.
- *Sensory ataxic GBS* due to involvement of roots and ganglionic neurons. In these patients, antibodies against the GD1b ganglioside have been found, suggesting that ataxic GBS and Miller-Fisher variants form a continuum and share autoantibodies with the same fine specificity of sialic groups.
- *Acute pandysautonomic neuropathy*.⁴ In these cases, there is no evidence of detectable demyelination, and the target antigen is probably a component of the autoimmune system and ganglionic neurons.

DIAGNOSIS

The classic laboratory abnormalities in GBS patients are elevated cerebrospinal fluid (CSF) protein and abnormal nerve conduction studies consistent with active demyelination.

The CSF protein may be normal in the early phase of the disease, but it can be as high as 1000 mg/dL by the sixth week of illness. The elevation of CSF protein may be due to involvement of the roots related to inflammation, but, as the blood-nerve barrier becomes impaired, serum albumin and IgG may enter freely into the CSF, contributing further to protein elevation. The CSF cell count is normal unless GBS occurs in a setting of HIV infection or in conjunction with other viral infections,

such as CMV or EBV. Mild lymphocytosis is not a sign against the diagnosis of GBS, but rather is suggestive of a coexisting viral illness or a lymphomatous process. When the CSF protein is very high, papilledema may develop because of impaired reabsorption of CSF and raised intracranial pressure. Oligoclonal IgG bands can be also seen.

The differential diagnosis of GBS should include other forms of acute flaccid paralysis, such as: brainstem stroke; brainstem encephalitis; acute paralytic poliomyelitis or West Nile Virus infection; acute myelopathy; other causes of acute neuropathy such as rabies-vaccine neuropathy, diphtheria, heavy metals, acute intermittent porphyria, vasculitis, critical illness neuropathy or lymphomatous neuropathy; disorders of neuromuscular transmissions such as myasthenia gravis, botulism, or other industrial toxins; and disorders of muscles such as hypokalemia, inflammatory myopathy, acute rhabdomyolysis, or periodic paralysis.

ANTECEDENT ILLNESSES OR EVENTS

Two-thirds of patients with GBS give a history of a flu-like illness with upper respiratory signs or acute dysenteric episodes that precede the development of GBS by 1–3 weeks.^{1,2} Among the implicated viruses are cytomegalovirus, Epstein-Barr virus (EBV), herpes viruses, outbreaks of hepatitis A, and HIV. Among bacteria *Mycoplasma pneumoniae* and, most importantly, *Campylobacter jejuni* are serologic markers of infection that may be present in 15–20% of patients. *Campylobacter* is of special interest because it contains glycoconjugates that share epitopes with the peripheral myelin. Cytomegalovirus (CMV) can directly infect the nerve and cross-react with GM2 glycolipid and Po protein of the peripheral nerve. Two vaccines – one against rabies and the other against the swine flu A/New Jersey influenza strain that caused an outbreak of GBS in 1976^{1,2} – have been convincingly connected with the development of GBS. Rabies vaccine that contains brain material is followed by GBS in about one in 1000 cases. Apart from these vaccines, however, there is no convincing evidence that the incidence of GBS is increased in connection with other vaccines, in spite of anecdotal reports of patients who developed GBS 1–3 weeks after vaccination.

Surgery can precede the development of GBS in up to 10% of patients.² Surgical stress, the release of nerve autoantigens, and infections have been proposed as possible explanations for this association.

There are only three drugs causally associated with acute demyelinating neuropathy: gold, perhexiline, and suramin.⁵ Other drugs cause a chronic or subacute axonal and predominantly sensory neuropathy. In the author's experience, suramin, when used at high doses for the treatment of prostatic carcinoma, caused acute GBS with respiratory involvement. The currently used lower doses of suramin, with concurrent monitoring of the drug levels, do not cause GBS but an axonal, mostly motor, neuropathy with predilection for the proximal muscles (Dalakas, unpublished observations).

GBS has occurred in patients who suffer from neoplasms, especially lymphoma, melanoma and Hodgkin's disease. Interestingly, in spite of the autoimmune nature of GBS, the disease is rarely seen as part of another connective tissue disorder.^{1,2}

IMMUNOPATHOLOGY

GBS is an inflammatory demyelinating polyneuropathy in which the peripheral myelin, the axon or the Schwann cells are the target antigens of an immune attack, possibly triggered by the various antecedent events

discussed above. Both the cellular and the humoral components of the immune system have been implicated in the immunopathogenesis of GBS. In spite of newly identified myelin antigens, the exact target antigen is still unknown.

CELLULAR FACTORS

The nerves of GBS patients possess two prominent histologic features: (1) perivascular and endoneurial inflammatory infiltrates consisting of lymphocytes and macrophages, found throughout the cranial nerves, ventral and dorsal roots, plexuses, and peripheral nerves;^{1, 2} and (2) segmental demyelination in areas associated with the lymphoid infiltrates. Although among the infiltrates CD4 T cells appear to predominate over CD8 T cells and macrophages, if one takes into account that 70% of tissue macrophages express CD4, the dominant cells are the macrophages. By electron microscopy, macrophages break through the basement membrane of healthy Schwann cells and make direct contact with the outermost myelin lamellae, leading finally to lysis of the superficial myelin sheath. Macrophages may exert their myelinolytic activity via lymphokines, especially interleukin (IL)-1. Interferon (IFN)- γ released by the activated T cells, or complement activation, may also serve as a chemotactic factor, increasing capillary permeability and enhancing recruitment of additional macrophages. When the demyelination is extensive, it is followed by axonal degeneration.^{1, 2} At sites of segmental demyelination there is a proliferation of Schwann cells along the denuded axons, whereas in areas of axonal degeneration the Schwann cells proliferate in columns to guide the regenerating axons. The proliferating Schwann cells are responsible for remyelination and axonal regeneration, which may begin even during the phase of active myelin breakdown. The degree and effectiveness of remyelination and axonal regeneration dictate the degree of clinical recovery.

A number of studies indicate that activated T cells play a role in GBS. Peripheral blood lymphocytes from GBS patients exert myelinotoxic activity when applied to cultures of myelinated axons. Further, levels of IL-2 and soluble IL-2 receptors are increased in the serum during the acute phase of GBS and decline during recovery, suggesting ongoing T-cell proliferation.

A more convincing role for a T cell-mediated process in GBS is derived by analogy to the animal model of experimental allergic neuritis (EAN), which resembles GBS in both its pathology and its clinical course. Animals sensitized to whole human nerve or to various myelin proteins such as Po, P2, and the neutral glycolipid galactocerebroside, develop segmental demyelination with mononuclear cell infiltrates consisting of macrophages and T cells. In EAN, the T cells are sensitized against myelin, and T cells from EAN animals or cloned P2-specific T-cell lines can passively transfer the disease to healthy animals.

HUMORAL FACTORS AND ANTI-GANGLIOSIDE ANTIBODIES

There is much stronger evidence that circulating serum factors are responsible for GBS. On clinical grounds, this is supported by the beneficial effect of plasmapheresis, presumably by removing putative antibodies. On laboratory grounds it is supported by the variety of autoantibodies detected in the serum of patients with acute GBS. This conclusion is based on the following observations. Serum from the acute phase of GBS can demyelinate rodent dorsal root ganglionic extracts in a complement-dependent manner. Further, GBS serum injected into rat

sciatic nerves causes demyelination and conduction block. Immunocytochemical studies on the peripheral nerves of GBS patients show deposits of IgG, IgM, and membranolytic attack complex, implying complement-fixing antibody activity of the serum immunoglobulin.² This observation is further supported by the report of complement-fixing IgM antibodies against a human neutral glycolipid of peripheral nerve myelin that contains carbohydrate epitopes as well as high-titer antibodies against various sulfated or acidic glycosphingolipids.^{6, 7}

Antibodies that react with GM1, GD1a, GalNAc-GD1a and GM1b are found in 80% of cases with motor axonal form of GBS (AMAN and AMSAN). In the common AIDP subtype, however, these antibodies are not frequent. Among the gangliosides, the one that clearly correlates with a specific clinical syndrome is the GQ1b.⁸ Anti-GQ1b IgG antibodies appear to be specifically associated with the C. Miller-Fisher variant of GBS because they are present in more than 90% of these patients. Anti-GQ1b IgG antibodies are also found in post-infectious ophthalmoplegias as well as in GBS patients with ophthalmoplegia, but not in GBS patients without ophthalmoplegia or in other autoimmune conditions.⁸ Of interest, anti-GQ1b antibody immunostains the paraventricular regions of oculomotor nerves III, IV, and VI, suggesting that damage to these regions blocks impulse generation at the nodes of Ranvier, resulting in a conduction block that is characteristic for GBS. Although anti-GQ1b antibodies have been found in patients with IgM paraproteinemic polyneuropathies (discussed later), in ophthalmologic GBS these antibodies are of IgG class and do not recognize other polysialo-gangliosides. In the author's judgment, anti-GQ1b IgG antibodies should be considered specific for the C. Miller-Fisher variant. Many patients with antibodies to GQ1b also have antibodies to GD1a.

It is important to emphasize that although anti-GM1 antibodies of IgM class are seen in other neuropathies, in GBS patients these antibodies are mostly of the IgG class.

In clinical practice, anti-ganglioside antibodies are identified by ELISA using purified gangliosides, but for more detailed analysis TLC (thin-layer chromatography) overlay is utilized. Gangliosides are present in all tissues but are especially abundant in the nervous system. Their lipid portion lies in the cell membrane, and their signature sugar residues are exposed at the extracellular surface bearing one or more sialic acid molecules, such as one sialic acid ganglioside (GM1), two (GD1a), three (GT1a) or four (GQ1b). Although they do not form a common 'GBS antigen,' different gangliosides are involved in different GBS subtypes. The antibodies against these gangliosides are of pathogenic relevance because immunization of rabbits with GM1 and GD11b induces acute neuropathy with histological features of AMAN.⁹ Their pathogenicity was also confirmed by an inadvertent experiment in humans who had received ganglioside injections for various maladies and developed AMAN with GM1 antibodies.¹⁰ Additionally, antibodies to GQ1b or GD1a cause conduction block at the motor nerve terminals in a preparation of mouse phrenic nerve.⁹ Similarly, antibodies to GalNAc-Gd1a from a patient with AMAN blocked neuromuscular transmission in a mouse spinal cord muscle co-culture system.

The reasons for different syndromes in connection with specific gangliosides remains unclear, but distribution and accessibility may be critical factors. The gangliosides are distributed differently within the peripheral nervous system, a phenomenon that could explain the different subtypes. For example, there is more GM1 in ventral than in dorsal roots, hence the predominantly motor neuropathy seen with GM1 antibodies; there is also more GQ1b in the ocular motor nerves, which

explains the eye involvement in Miller-Fisher syndrome. In addition to distribution, accessibility of the ganglioside antigens to the immune system and the density or configuration of ganglioside at different sites are also critical factors. What remains unclear is why the anti-ganglioside antibodies in AMAN and Miller-Fisher syndrome are almost invariably of the IgG₁ or IgG₃ subclass, which are thought to require T-helper cell involvement for a class switch from IgM, whereas conventional T cells do not respond to glycolipids.

How these antibodies induce disease remains also unclear. They may activate the immune system directly because they have the capacity to react with Fcγ receptors of macrophages, and also activate neutrophils *in vitro*. Opsonization of antigens on the axonal surface could enable macrophages to target the respective antigens. Current evidence suggests that antibodies against different acidic glycolipids or sulfatides may be related to the different viral or bacterial antecedent factors. Molecular mimicry between epitopes of viral proteins (which trigger the disease) and myelin components may result in sensitization of cross-reactive T cells that could mediate the demyelinating process. The activated T cells may then stimulate B cells to produce specific antibodies directed against myelin components, or may recruit macrophages as effector cells. A combination of cellular and humoral factors therefore seems to participate in the cause of the disease. Circulating cytokines triggered by the initiating event (virus, bacteria) could also upregulate intercellular adhesion molecule (ICAM)-1 expression on the endothelial cells and facilitate the entrance of activated T cells or antibodies, even of the IgM class, to the endoneurial parenchyma. It is relevant, therefore, that ICAM-1 has been found to

be increased in GBS patients. A scheme summarizing that immunopathogenic mechanism is shown in Figure 66.1

MOLECULAR MIMICRY AS A PATHOGENIC FACTOR: RELATIONSHIP BETWEEN *C. JEJUNI* OR OTHER MICROBIAL AGENTS WITH GANGLIOSIDES

Antecedent infection with *Campylobacter* in GBS patients has been associated with more severe disease and marked residual disability. Subsequent studies showed that GBS is associated with *C. jejuni* (Penner D: 19 Serogroup) in 15–46% of GBS patients. Further, such patients also had a higher incidence of anti-GM1 antibodies, a higher incidence of axonal damage, and poorer recovery, indicating a cross-reactivity between epitopes in the lipo-oligosaccharide in the bacterial wall and ganglioside.¹¹ Because these bacteria are a common cause of a diarrheal illness worldwide, and diarrhea has been an antecedent event in up to 50% of GBS patients, infection with *Campylobacter* may trigger the disease in some patients. Isolation of *Campylobacter* from stools early in acute GBS varies from 44% to 88% of patients, and IgG or IgM *Campylobacter*-specific antibody titers are seen in a higher percentage (36%) of GBS patients than in controls (10%).

C. jejuni infection is followed by a clinical subtype of GBS as mentioned earlier, but it is more common with AMAN because after infection with *C. jejuni* axonal damage is more common. The strain of *C. jejuni* that causes AMAN is different from those causing common enteritis and is more likely to have the genes for enzymes that synthesize

Fig. 66.1 Sequence of events in the mechanisms of immune-mediated demyelinating polyneuropathy. Cytokines lead to increased expression of major histocompatibility complex (MHC) class I and intercellular adhesion molecules, allowing the sensitized T cells and macrophages to exit the endothelial cell wall and traffic to the peripheral nerve. There, they recognize myelin antigen and induce a macrophage-mediated demyelination. The antigen-presenting cells (probably Schwann cells or macrophages), in concert with MHC class II expression, interact with CD4 T cells and lead to clonal expansion of B cells, producing antibodies against various peripheral nerve antigens.

sialic acid in the bacterial wall mimicking ganglioside GM1, GD1a or GQ1b. The causal relationship was recently confirmed when injection of lipo-oligosaccharides extracted from *C. jejuni* into rabbits induced an acute neuropathy with GM1 antibodies identical to those of AMAN.⁹ Further, immunization of mice with these lipo-oligosaccharides generated a monoclonal antibody that reacted with GM1 and bound to human peripheral nerve. Additionally, this monoclonal antibody as well as the anti-GM1 IgG extracted from GBS patients blocks muscle action potentials in muscle-spinal cord co-culture. Carbohydrate mimicry between the bacterial lipo-oligosaccharide and human GM1 is therefore an important cause of AMAN. Molecular mimicry may not be limited to *C. jejuni* because GM1 and GQ1b epitopes are also in the bacteria wall of *Hemophilus influenzae*, which is also a triggering factor in GBS. GBS triggered by CMV infection has been also associated with the presence of IgM anti-GM2 antibodies, even though the distribution of GM2 on human myelin sheath and peripheral nerve is unclear. Another potential

factor for molecular mimicry is *Mycoplasma pneumoniae*, which precedes GBS in 5% of cases and is known to stimulate antibodies against human carbohydrate antigens, including galactocerebroside, the main glycolipid antigen in the peripheral nerve.

CHRONIC INFLAMMATORY DEMYELINATING POLYNEUROPATHY

Chronic inflammatory demyelinating polyneuropathy (CIDP) is the most common form of chronic APN. It can be considered as the chronic counterpart of GBS because of their various clinical, electrophysiologic, histologic, and laboratory similarities. CIDP differs from GBS predominantly by its tempo, mode of evolution, prognosis, and responsiveness to steroids. First described as steroid-responding relapsing polyneuropathy, CIDP shares with GBS a variety of common autoimmune features.

KEY CONCEPTS

AUTOIMMUNITY IN GUILLAIN-BARRÉ SYNDROME

Cellular factors

- >> The peripheral myelin or the Schwann cells are target antigens.
- >> Activated macrophages are the dominant endoneurial cells and lift the outermost myelin lamellae, lysing the superficial myelin sheaths.
- >> Peripheral blood lymphocytes exert myelinotoxic activity *in vitro*.
- >> Levels of IL-2 and soluble IL-2 receptors are increased during the acute phase of the disease and decline during recovery.

Humoral factors

- >> Serum exerts a complement-dependent demyelination *in vitro*.
- >> Intraneural injections of serum from acute GBS patients cause demyelination and conduction block.
- >> IgG, IgM, and membranolytic attack complex are detected immunocytochemically on the patients' nerves.
- >> High titers of IgG antibodies against peripheral nerve acidic glycolipids (GM1, GQ1b) are detected in the serum of AMAN and Miller-Fisher's syndrome. The GQ1b ganglioside is a specific antigen for Miller-Fisher's syndrome.
- >> High incidences of antibodies to *Campylobacter jejuni* and GM1, with molecular mimicry between *Campylobacter* and nerve gangliosides.
- >> Injection of lipooligosaccharides extracted from *Campylobacter jejuni* cause AMAN and elicit GM1 antibodies in rabbits.
- >> Anti-ganglioside antibodies extracted from GBS patients block muscle action potentials *in vitro*.

CLINICAL FEATURES

CIDP presents with a slowly progressive weakness and paresthesias that evolve over 4–6 weeks or several months. Maximum deficit is usually reached after 2 months from onset^{12,13} Although initially the weakness is predominantly distal, proximal muscle involvement can be prominent, especially late in the disease course. CIDP can be either monophasic or characterized by spontaneous remissions and relapses. With early initiation of therapy, it is difficult to distinguish true spontaneous relapses from pharmaco-relapses.¹³

DIAGNOSIS

Although a variety of diagnostic criteria have been proposed and are continuously revised, the author's original criteria¹³ are by all accounts still the most definitive characteristic diagnostic signs for the disease. They include:

- Subacute onset of sensorimotor polyneuropathy, which is progressive over several weeks or months, or has a relapsing–remitting course.
- Absence of another systemic disease that can cause neuropathy. Specifically, the patient should not have diabetes, thyroid disease, neoplasms, amyloidosis, paraproteinemia, myelomas, vasculitis, alcoholism, collagen–vascular disease, systemic infections, exposures to neurotoxic agents or drugs, or family history of neuropathy. Although CIDP can occur in a patient who is diabetic, alcoholic or HIV positive, or who has an IgG or IgA benign gammopathy, for a strict definition, all these diseases should be excluded.
- Elevated CSF protein, up to sixfold, without pleocytosis. When CIDP is developed in an HIV-positive patient, pleocytosis is common. No oligoclonal bands are found, but a single band is often seen on agarose gel electrophoresis, probably reflecting the high amount of protein.
- Demyelination of motor and sensory fibers by electrophysiologic testing or nerve biopsy (Fig. 66.2).¹² Although nerve biopsy is not necessary when the electrophysiology is characteristic for CIDP, it can be a useful aid in studying the immunopathology of the disease. Nerve conduction velocity is, as a rule, slow (at least <60% of normal), the F-wave latencies are prolonged, the distal motor and sensory latencies

Fig. 66.2 (A) The co-stimulatory molecule BB-1, but not B7-1 or B7-2, is expressed on S-100-positive Schwann cells. (From Murata and Dalakas, *Brain* 2000.)

are prolonged, and an associated conduction block in one or more nerves, with dispersion of the compound muscle action potentials, is noted.¹³ An associated axonal loss is not unusual; in the majority of cases needle electromyography (EMG) shows denervation.

As several therapeutic studies have been carried out in CIDP, variations of the diagnostic criteria have been introduced. In all cases, however, it appears to be consensus that CSF examination and nerve biopsy are not mandatory.

CIDP may mimic the following APN: (1) the multifocal motor neuropathy with conduction block,¹⁴ when the sensory findings are not prominent; (2) the demyelinating neuropathies associated with IgA or IgG gammopathies; (3) the intermediate form of GBS when the onset of GBS is not very acute and its maximum deficit is reached between 4 and 8 weeks; and (4) the relapsing form of GBS. Up to 3% of GBS patients relapse,² but in some cases the new relapse may not be as acute and typical as the original attack but slower, resembling the intermediate form. Variants of CIDP have been recently recognized.¹⁴ These include a multifocal sensorimotor but asymmetric form, and a multifocal regional form with a predominantly upper or lower limb involvement.

KEY CONCEPTS

AUTOIMMUNITY IN CIDP

- >> Activated macrophages are the predominant endoneurial cell, displacing the Schwann cell cytoplasm, disrupting myelin, and lyzing superficial myelin lamellae.
- >> Complement-fixing IgG and IgM antibodies are deposited on the myelin sheath.
- >> IgG antibodies to acidic glycolipids LM1, GM1, or GD1b and against the 28 kDa Po myelin proteins, are detected in the serum of some patients.
- >> There is upregulation of DR and B-7 co-stimulatory molecules in the Schwann cells and macrophages.
- >> The serum IgG can induce conduction block when injected into rat nerves.

B

Fig. 66.2 Cont'd (B) The counter-receptors CD28 and CTLA-4 are upregulated on CD4-positive T cells. At the mRNA level, there is upregulation of CD28 and CTLA-4. (Murata K, Dalakas MC Expression of co-stimulatory molecules BB-1, the ligands CTLA-4 and CD28 in patients with chronic inflammatory demyelinating polyneuropathy. *Brain* 2000; 123: 1660–1666.)

In contrast to GBS, patients with CIDP do not have increased incidence of infections, vaccinations, or traumas preceding the development of the neuropathy. The significance of a few isolated case reports that followed an infectious illness¹³ is unclear. CIDP is a chronic disease; although it responds to immunotherapies, a number of patients have incomplete recovery and are left with residual weakness.¹⁴

IMMUNOPATHOGENESIS

Although CIDP is defined as an inflammatory polyneuropathy, there are only minimal signs of inflammation with hematoxylin and eosin stains in the sural nerve biopsies. The T-cell populations that have been identified are heterogeneous, belonging to both CD4 and CD8 T subsets. Elevated soluble adhesion molecules, chemokines, cytokines and metalloproteinases are detected in the sera and CSF, and this facilitates lymphoid cell

transmigration across the blood–nerve barrier. Within the endoneurium cytokines activate the resident macrophages that appear to be the predominant endoneurial mononuclear cell in CIDP nerves.¹² Electron-microscopic studies have demonstrated that the demyelinating process in CIDP is always associated with the presence of macrophages, which sequentially penetrate the basement membrane of the Schwann cell, displace the cytoplasm, and finally disrupt the myelin by focal lysis of the superficial myelin lamellae.¹² Similarities may exist in this regard with GBS and the chronic or relapsing–remitting form of experimental allergic neuritis, in which macrophages, activated T cells, and deposits of membranolytic attack complex C5b-9 are noted on the myelin sheath. In CIDP, macrophages and Schwann cells may serve as antigen-presenting cells. They express HLA-DR and co-stimulatory molecules B7-1, B7-2, whereas their counter-receptors CTLA-4 and CD28 are expressed on rare endoneurial CD4 T cells¹⁵ (Fig. 66.2A and B). The cellular immune response appears to be tightly regulated at the transcriptional level, as

Fig. 66.3 Diagrammatic scheme of the main cellular elements that seem to play a major role in the demyelinating process of CIDP. Activated macrophages (Mφ) and T cells cross the endothelial cell wall of the blood-nerve barrier and reach the myelinated fibers. Activated, TNF-α-positive Mφ invade the myelin sheath, causing Mφ-mediated segmental demyelination. Axonal loss secondary to demyelination, probably enhanced by TNF-α and metalloproteinases, may become prominent in the chronic phases of the disease. Other cytokines, T cells sensitized to unidentified antigens and putative antibodies may participate. IL, interleukin; INF, interferon; MMP, metalloproteinase; Mφ, activated macrophage; TNF, tumor necrosis factor.

supported by the activation of the transcriptional factor NF-κB in the macrophages.

Humoral factors may play a major role in CIDP. Complement-fixing IgG and IgM are deposited on the patient's myelin sheath, indicative of antimyelin antibodies.¹⁶ Antibodies to glycolipids LM1, GM1, or GD1b are also seen in some CIDP patients, but less frequently than in GBS patients and more frequently than in the controls. Serum reactivity against nonmyelin antigens on Schwann cells has been reported in 12 of 45 patients, and passive transfer experiments have demonstrated that serum IgG can induce conduction block in rat nerve. The 28 kDa myelin protein Po was identified as a putative antigen in up to 20% of the patients. Finally, the beneficial effect of plasmapheresis may be indirect evidence that circulatory factors play a pathogenetic role. The immunopathogenetic scheme proposed for GBS (Fig. 66.1) is also appropriately applied to CIDP, with some modification to denote the axonal loss that accompanies the demyelination (Fig. 66.3).

Molecular mimicry can be implicated in CIDP associated with melanoma. Carbohydrate epitopes such as GM3, GM2, GD3 are expressed on melanoma, and antibodies against melanoma cells react with myelin glycoproteins. A molecular mimicry was demonstrated in a patient with CIDP between the GM2-positive melanoma cells and the peripheral myelin because her serum recognized GM2 epitopes present in both the nerve and the tumor.¹⁷

■ PARAPROTEINEMIC POLYNEUROPATHIES ■

A distinct subset of acquired polyneuropathies has been associated with a circulating monoclonal protein (Chapter 78). Although neuropathy occurs in a setting of myeloma, plasmacytoma, or Waldenström's macroglobulinemia, the majority of paraproteinemic neuropathies occur in patients without an underlying lymphoproliferative disease. The

gammopathy in such patients is of undetermined significance, even though most of the time the IgM monoclonal protein recognizes specific antigenic determinants of the human myelin.

Until 1979, the association of neuropathy with benign monoclonal gammopathy was thought to be rare and coincidental because a causal relationship between the neuropathy and the paraproteinemia had not been established. Further, benign gammopathies occur, nonspecifically, in many chronic inflammatory or infectious conditions, and their incidence increases with age, occurring in up to 2% of normal people over 70 years of age. In 1979, in the largest series of 11 such patients,¹⁸ the author stressed that this is a distinct immune-mediated association because the paraprotein binds to peripheral nerve, and in a number of patients the neuropathy responds to immunosuppressive therapy. Two years later, the causal association between the paraprotein and the neuropathy was strengthened when it was shown that the monoclonal IgM of a patient with demyelinating polyneuropathy had a specific anti-myelin activity directed against myelin-associated glycoprotein (MAG).¹⁹ Today, polyneuropathies with monoclonal gammopathy comprise 10% of patients with acquired neuropathy,^{20, 21} and paraproteinemic polyneuropathy is a potentially treatable APN.

A monoclonal gammopathy is considered benign when the patients have the following: (1) <3 g/dL of monoclonal protein in their serum and rarely the same monoclonal protein in the urine; (2) <5% plasma cells in the bone marrow aspirate; (3) no systemic signs of renal insufficiency, osteolytic or osteosclerotic lesions in the bone survey, or signs of anemia and hypercalcemia; (4) no suppression of the rest of the uninvolved polyclonal immunoglobulins (background immunoglobulins); (5) no signs of a lymphoproliferative disease; and (6) a stable amount of the monoclonal protein during follow-up examinations. In contrast, ominous signs of malignant plasma cell dyscrasia are lytic bone lesions, Bence Jones proteinuria, a reduction of the uninvolved (background) immunoglobulin level, abnormal bone marrow examinations, and a progressively increased amount of monoclonal protein in serial measurements. Even in the benign gammopathies, however, there is a 1% probability per year that a malignant plasma cell dyscrasia may evolve,²² hence the need for periodic screening.

A free light chain is more often associated with amyloidosis. If it is present in a patient with gammopathy and neuropathy, deposits of amyloid should be thoroughly sought in the nerve, muscle, skin, abdominal fat or bone marrow.

FREQUENCY OF POLYNEUROPATHIES IN PATIENTS WITH MONOCLONAL GAMMOPATHY

A benign monoclonal gammopathy may occur in up to 1% of normal people over 50 of age.¹⁷ The incidence increases to 1.7% above age 70 and reaches up to 6% above the age of 90.²² Monoclonal gammopathies, however, are 10 times more frequent in patients with polyneuropathy than in an age-matched control population, and almost 10% of patients with acquired polyneuropathy have an associated monoclonal gammopathy.²⁰ If one categorizes these gammopathies into subclasses, the incidence of polyneuropathy among patients with IgM monoclonal proteins can be as high as 50%,²¹ implying that almost 50% of patients with IgM monoclonal gammopathy may have or will develop polyneuropathy. The association of monoclonal gammopathy with peripheral neuropathy is not therefore fortuitous.

Some patients with paraprotein may have an associated amyloidosis derived from the variable region of the immunoglobulin light chain.

When amyloidosis is present, the neuropathy is often painful and has a strong autonomic component. In addition to painful paresthesias in the hands and feet, these patients have mild to moderate distal weakness, often with pedal edema, and autonomic symptoms consisting of orthostatic hypotension, dizziness, impotence, impaired gastric motility, or frequent diarrhea. The disease is difficult to treat, and, apart from symptomatic therapy (mostly opiates), immunosuppressive therapies have been largely unsuccessful. The diagnosis is made via a muscle or nerve or fat biopsy that demonstrates amyloid deposits in the connective tissue or around blood vessels. In the author's hands, the muscle and skin biopsy has a higher yield than nerve biopsy for finding amyloid deposits.

POLYNEUROPATHIES ASSOCIATED WITH IgG OR IgA MONOCLONAL GAMMOPATHIES

Patients with polyneuropathy and benign IgG or IgA monoclonal gammopathy usually have an axonal neuropathy, and their IgG or IgA does recognize specific neuronal or myelin antigens. Sometimes, when the neuropathy is demyelinating, it behaves like CIDP and responds to immunotherapy. The causal association between the monoclonal protein and neuropathy in these patients has not been established. The monoclonal spike may represent a nonspecific response to a chronic inflammatory process, or it may be due to an underlying lymphoproliferative disease that is slow and restrained.

POLYNEUROPATHY, ORGANOMEGALY, ENDOCRINOPATHY, MYELOMA, AND SKIN CHANGES (POEMS)

A subset of patients with malignant IgG or IgA gammopathy have polyneuropathy with osteosclerotic myeloma. Most of them comprise the POEMS syndrome (*p*olyneuropathy, *o*rganomegaly, *e*ndocrinopathy, *M* protein, and *s*kin changes).²³ Not included in the acronym are several features such as sclerotic bone lesions, Castleman's disease, papilledema, pleural effusion, edema, ascites and thrombocytosis.²³ More than 50% of patients with osteosclerotic myeloma of IgA or IgG type have a sensorimotor, symmetric polyneuropathy with mixed demyelinating and axonal features and high (usually 200 mg/dL) CSF protein.²³ Pure axonal neuropathies can be also seen. In POEMS the neuropathy tends to be associated with edema in the legs, with hyperpigmentation, scleroderma-tous thickening or papular angiomas of the skin, and hypertrichosis with dark hair.²³ Endocrinopathy most often includes gonadal failure, amenorrhea, impotence, gynecomastia, hypothyroidism, diabetes, or elevated prolactin levels. The IgG class is slightly more common than the IgA class, but the λ light chain is present in the majority (up to 95%) of the patients.²³ Computed tomography (CT) of the abdomen may reveal an enlarged spleen and calcifications. The bone lesions can be sclerotic, solitary, or multiple, sparing the skull and the extremities. Pathologic changes in the lymph nodes, which can also be enlarged, may at times resemble those of Castleman's disease, which can also be associated with polyneuropathy.²³ Not all patients with POEMS, however, have all these features. When sclerotic lesions are absent, patients are said to have Crow-Fukase syndrome.²⁴ POEMS appears to be mediated by an imbalance of proinflammatory cytokines. IL-1b, IL6 and TNF- α are increased. Vascular endothelial growth factor (VEGF) may play a major role because it induces a rapid increase in vascular permeability and is a growth factor important in angiogenesis and endothelial cells.^{23, 24}

The neuropathy in some patients responds to steroids, tamoxifen, or alkylating agents. In others, it may respond to the removal or irradiation of the solitary sclerotic lesion, suggesting that the tumor may secrete neurotoxic factors, perhaps neurotoxic light chains. IVIG and plasmapheresis are ineffective. The role of autologous stem cell transplantation or cytokine modulation remains untested. The median survival is 165 months.²³

POLYNEUROPATHIES ASSOCIATED WITH IgM MONOCLONAL GAMMOPATHIES

This entity is composed of an immunochemically and clinically heterogeneous group of neuropathies in which the immunoglobulin appears to be an antibody to various glycoproteins or glycolipids of the peripheral nerve. These neuropathies can be best divided into the following subsets.

- Demyelinating polyneuropathy with IgM anti-MAG or ganglioside antibodies.** Sera from approximately 50% of patients with IgM monoclonal gammopathy and neuropathy react with myelin-associated glycoprotein (MAG), a 100-kDa glycoprotein of the central and peripheral nerve myelin, as well as other glycoproteins or glycolipids that share antigenic determinants with MAG.²¹ Most patients with anti-MAG antibodies present with a sensory, large-fiber, demyelinating polyneuropathy that manifests as sensory ataxia.²⁵ Other patients have a sensorimotor polyneuropathy with mixed features of demyelination and axonal loss. The CSF protein is elevated, up to 250 mg/dL (normal is ≤50 mg/dL). The monoclonal IgM may also enter the CSF compartment, in spite of its high molecular weight, via dorsal root ganglia that lack a blood-CSF barrier or from a disrupted root-CSF barrier. Nerve conduction studies demonstrate slow conduction velocity and a rather characteristic prolonged distal motor and sensory latency. Sural nerve biopsy demonstrates a diminished number of myelinated axons (Fig. 66.3). Lymphocytic infiltrates are rarely seen within the endoneurial parenchyma. On electron microscopy there is splitting of the outer myelin lamellae, linked to the presence of IgM deposits in the same area of the split myelin sheath.²⁶
- Anti-MAG and SGPG antibodies.** MAG is the most extensively studied antigen recognized by the IgM paraproteins. The antigenic determinant for the anti-MAG IgM paraprotein resides in the carbohydrate component of the MAG molecule, as demonstrated by the loss of reactivity following deglycosylation of purified human MAG²⁷ (Fig. 66.4). An important finding was the observation that the anti-MAG IgM paraproteins co-react with an acidic glycolipid in the ganglioside fraction of the human peripheral nerve, which is separated from the whole ganglioside fraction by ion-exchange chromatography.²⁸ This antigenic glycolipid, chromatographed between GM1 and GD1a, has been identified as a sulfoglucuronyl glycosphingolipid, SGPG (Fig. 66.5). In contrast to MAG, which is mostly present in the CNS, SGPG is found only in peripheral nerves.
- Anti-ganglioside antibodies.** The sera of some patients with IgM monoclonal gammopathy and demyelinating polyneuropathy may not react with MAG, in spite of clinical similarities to the anti-MAG-reacting paraproteins, but with various gangliosides. Most common gangliosides reacting with IgM, especially in patients with

Fig. 66.4 Immunoblots showing binding of IgM to purified human MAG. Immunoblots of sodium dodecyl sulfate gels with purified rat MAG in lane 1 (R) and purified human MAG in lane 2 (H). **(A)** Purified MAG 10 µg in each lane are stained for protein with amido black; **(B)** 500 ng of purified MAG in each lane immunostained with a 1:50 dilution of serum from a patient with IgM monoclonal gammopathy, followed by peroxidase-labeled goat antihuman IgM; **(C)** the same blots, loaded as in (B) but stained with the mouse IgM monoclonal antibody produced against human MAG, are visualized by peroxidase-labeled goat anti-mouse IgG and IgM.

pure sensory neuropathies, are those that contain either a disialosyl moiety, such as GD1b, GQ1b, GT1b, the GalNac-GM1b and GalNac-GD1a, or two gangliosides that share epitopes with GM2, or a combination of GM2 and GM1, GM1 and GD1b.^{29,30}

- Motor, axonal neuropathies or neuronopathies with monoclonal IgM anti-GM1-antibodies.** A small number of patients with IgM paraprotein have a predominantly motor neuropathy that resembles a lower motor neuron syndrome. The IgM in some of these patients shows strong immunoreactivity to GM1 and asialoGM1 and, to a lesser degree, to GD1b. Because GM1 is present on the surface of motor neurons and the nodes of Ranvier, these findings led to a search for polyclonal GM1 antibodies in patients with a variety of conditions, including motor neuron diseases, multifocal motor neuropathy with conduction block, and Guillain-Barré syndrome and CIDP.

Fig. 66.5 Thin-layer chromatography overlay experiments demonstrating the reactivity of an anti-MAG monoclonal antibody from a neuropathy patient with glycolipid antigens of human sciatic nerve. The panel on the left shows the resorcinol-stained ganglioside fractions (10 µg sialic acid) isolated from human brain (CNS left lane) and human sciatic nerve (PNS right lane). The prominent chromatography GM1 and GD1a gangliosides of brain and LM1 ganglioside of nerve are labeled for reference. The panel on the right is an autoradiograph obtained after overlaying the same TLC plate with the patient's serum followed by radiolabeled anti-human IgM. The major glycolipid antigen in the PNS is indicated by the arrow, and two minor glycolipid antigens are seen migrating just above and below the major antigen.

CAUSAL RELATIONSHIP BETWEEN ANTI-MAG ANTIBODIES AND NEUROPATHY

Because MAG is present in small amounts in the peripheral nervous system (PNS) but abundant in the CNS, which is spared in these patients, it was suggested that the reactivity of IgM to MAG may represent nonspecific binding to carbohydrate antigens. However, the discovery of the PNS-specific glycolipid SGPG, with which all the anti-MAG-reacting monoclonal IgMs react immunologically, has led to the proposal that the glycolipids, rather than the glycoproteins, may serve as primary antigenic targets. More than half of the IgM paraproteins recognize MAG and SGPG, and 75% of the rest recog-

Fig. 66.6 Cross-section of a sural nerve from a patient with IgM paraproteinemia and demyelinating polyneuropathy. Fresh-frozen nerve specimen stained with FITC-conjugated antibodies to human IgM reveals IgM deposits in many myelinated fibers.

nize ganglioside antigens, indicating that acidic glycolipids are the most common antigenic epitopes. Although the role of these antibodies in the pathogenesis of the neuropathy remains still unclear, the following factors suggest that they are related to the cause of the neuropathy:

- IgM and complement are deposited on the homologous myelinated nerve fibers on the patient's sural nerve biopsy,^{18,31} which suggests that activated complement may be needed in the induction of demyelination (Fig. 66.6).
- The IgM recognizes neural cell adhesion molecules and co-localizes with MAG on the areas of the split myelin lamellae,²⁶ suggesting involvement in myelin disadhesion. Skin biopsies from these patients have also confirmed the presence of IgM, complement C3d, and MAG deposition on the dermal myelinated fibers and the concurrent loss of nerve fibers.³²
- Injection of serum from patients with IgM anti-MAG/SGPG paraprotein supplemented with fresh complement into feline peripheral nerve causes complement-dependent demyelination and conduction block within 2–9 days of the injection.³³ The IgM injected intraneurally also localizes to the outer layer of the myelin sheath. Moreover, systemic transfusion of anti-MAG IgM paraproteins produces segmental demyelination in chickens,³⁴ with deposition of IgM on to the outer lamellae of the myelin along with splitting of the myelin lamellae, similar to that observed in the human neuropathy.

KEY CONCEPTS

AUTOIMMUNITY IN POLYNEUROPATHY WITH IGM MONOCLONAL GAMMOPATHY

- >> In more than 50% of patients IgM is an antibody against two antigens, myelin-associated glycoprotein (MAG) and glycosphingolipid SGPG.
- >> In many patients with non-MAG-reacting monoclonal IgM, the IgM recognizes (a) gangliosides containing disialosyl moieties, including GM1, GM2, GD1b, GD1a, and LM1; (b) sulfatides; and (c), rarely, chondroitin sulfate.
- >> Overall, in at least 75% of patients the IgM recognizes gangliosides that appear to be the primary antigenic targets.
- >> The IgM is deposited on the homologous myelin sheath and fixes complement.
- >> The IgM, when deposited on the myelin sheath, results in disadhesion and separation of the myelin lamellae and disruption of normal myelin function.
- >> Intraneural injection of anti-MAG-reacting IgM or passive transfusion into experimental animals causes segmental demyelination, whereas complement-fixing IgM is immunolocalized to the myelin sheath, causing myelin separation.

METHODS FOR DETECTING ANTI-MAG AND ANTIGLYCOLIPID ANTIBODIES

Human anti-MAG antibodies can be detected readily in sera by ELISA, or preferably by standard Western blotting procedures after electrophoresing purified MAG, isolated myelin, or whole brain homogenates. Because anti-MAG-reacting sera always recognize the SGPG glycolipid, the assay has been often performed using SGPG as antigen instead of purified human MAG. It is preferable, however, to use MAG as the target antigen rather than SGPG, because the IgM monoclonal anti-MAG antibodies bind to MAG 10–100 times more strongly than to SGPG antigen. Low-affinity anti-MAG antibodies can therefore be missed if SGPG is used as the antigen in the assay. The glycolipids implicated as antigens in immune-mediated neuropathies are depicted in Figure 66.7.

Cryoglobulinemic neuropathy

Cryoglobulins are proteins that precipitate in the cold and re-dissolve when heated (Chapter 78). There are three types of cryoglobulin: type I, which is monoclonal often of the IgM and IgG class; type II, which is mixed polyclonal with one monoclonal (often monoclonal IgM with polyclonal IgG); and type III, which is polyclonal (often IgM and IgG).

Polyneuropathy occurs most often with mixed cryoglobulinemias and presents as distal, sensory, symmetric polyneuropathy or as mononeuropathy multiplex. These patients also have purpura, polyarthralgias, cutaneous vasculitis, Raynaud's phenomenon, renal involvement with proteinuria, and polyneuropathy. Type II

Fig. 66.7 Glycolipids implicated as antigens in immune-mediated neuropathies. Sulfate-3-glucuronyl paragloboside (SGPG) is the glycolipid sharing a carbohydrate epitope with myelin-associated glycoprotein (MAG), and the terminal sulfated glucuronic acid is a key part of the epitope. GM1 is the ganglioside implicated in motor nerve disorders, and in most cases the terminal Gal (β 1-3) GalNAc epitope, which is shared with GD1b, is involved. The disialosyl moiety implicated in sensory neuropathies consists of NeuAca2–8NeuAc– and is present in GD1b and GT1b gangliosides, as well as the simpler GD2 and GD3 gangliosides (not shown). GQ1b ganglioside, which is the target antigen in C. Miller-Fisher syndrome, has two disialosyl moieties. Although GD1a ganglioside has two sialic acid residues they are not linked to each other, so antibodies to GD1a do not cross-react with the anti-GD1b antibodies. The color-coded sugar moieties represent key aspects of the various epitopes, but carbohydrate sequences recognized by the antibodies may include additional sugar residues. GlcUA, glucuronic acid; Gal, galactose; GlcNAc, N-acetylglucosamine; Glc, glucose; GalNAc, N-acetylgalactosamine; NeuAc, N-acetylneuraminic acid (sialic acid).

cryoglobulinemia may be associated with an underlying lymphoproliferative process. An increased incidence (up to 90%) of hepatitis C virus infection has been reported in patients with mixed cryoglobulinemia. This association is of more than theoretical interest because these patients are being treated with IFN- α , which is an effective drug for hepatitis.

The neuropathy is often axonal. The nerve biopsy shows perivascular inflammatory cuffing with axonal degeneration.

MULTIFOCAL MOTOR NEUROPATHY WITH CONDUCTION BLOCK

Multifocal motor neuropathy (MMN) presents with progressive weakness, atrophy, and areflexia in muscle groups supplied by many individual peripheral nerves (multifocal).³⁵ It differs from vasculitic neuropathy because it is slow and painless, and clinically affects only the motor nerve fibers. It also differs from a lower motor neuron disease because it progresses very slowly, over years, rather than over months as in motor neuron disease, and the distribution of the weakness is not multisegmental but within distributions of peripheral nerves. Further, in contrast to motor neuron diseases, weak muscles may not be always atrophic. In MMN the cranial musculature is often spared: noted atrophy of the tongue or the face is the exception. As in motor neuron disease, however, patients with MMN can experience cramps and fasciculations. The weakness and atrophy begin in the hands and are more prominent distally. There is no evidence of other systemic illness. The CSF protein is normal, an important finding that distinguishes MMN from CIDP.

MMN is a distinct disease that should be recognized because it is treatable. It affects males more than females, and is more common in those under 50 years of age. It has distinct electrophysiologic criteria, namely, multifocal conduction block in motor nerves, with preservation of the sensory responses. In up to 50% of patients high GM1 antibody titers can be seen. In contrast to CIDP, in which sensory conduction block is also present, in MMN the sensory conduction remains normal across the nerve segments that have a severe motor block. The reason for a selective motor conduction block is unclear. Differences in the antigenic specificities in the myelin components between the motor and the sensory fibers are suspected because the ceramide composition of gangliosides differs between sensory and motor fibers.

The role of GM1 antibodies in the pathogenesis of MMN and as an aid in the distinction of MMN from CIDP or ALS is unclear. It has been proposed that the IgM anti-GM1 antibodies, by binding to GM1, may interfere with saltatory conduction; further, in an unconfirmed experiment, serum from an MMN patient with anti-GM1 antibody produced conduction block and demyelination when injected into the sciatic nerves of rats. In further experiments GM1 antibody-mediated conduction block has not been demonstrated, and GM1-binding sites have not been co-localized with voltage-gated sodium channels at the nodes of Ranvier. Further, high IgM GM1 antibody titers can be seen in other dysimmune neuropathies and in up to 25% of ALS patients who do not have conduction block.

Although the immunopathology of the disease is still unclear and the role of GM1 antibodies uncertain, MMN patients respond remarkably well to immunotherapy, as discussed later.

PARANEOPLASTIC PERIPHERAL NEUROPATHIES WITH ANTI-HU ANTIBODIES

Peripheral neuropathy is not an uncommon complication of cancer, related either to the systemic effects of the tumor or, more often, to various neurotoxic chemotherapeutic agents. The cancer-associated peripheral neuropathy is usually mild, axonal, and at times painful, and affects mostly the small nerve fibers. It is thought to be toxic and difficult to distinguish from the coexisting toxic neuropathy of the chemotherapeutic drugs. There is, however, a distinct sensory paraneoplastic neuropathy that has a unique clinical picture and possible autoimmune pathogenesis, the paraneoplastic sensory neuronopathy (PSN).

PSN is most often associated with small-cell lung cancer, and to a lesser degree with breast cancer or other neoplasms.³⁶ Most often, it is the presenting symptom and precedes the discovery of the tumor by months. PSN is most common in females and presents with a unique clinical picture, characterized by burning or aching paresthesias; sensory loss of the large fibers, causing sensory gait ataxia and chorioathetotic movements related to loss of proprioception in the feet and hands; normal strength; and areflexia. Some patients may have a varying degree of other associated neurologic signs, including autonomic dysfunction, encephalopathic symptoms, or cerebellar disturbances. Laboratory studies show increased CSF protein, an axonal sensory neuropathy by electrophysiologic testing, and an axonal degeneration with rare mononuclear cell infiltrates in the nerve biopsy. PSN is a ganglionopathy (sensory neuronopathy) due to involvement of the dorsal root ganglionic neurons. Histologically, there is a variable degree of inflammation in the dorsal root ganglia.

The autoimmune nature of PSN is supported by the presence of specific IgG antibodies, the anti-Hu autoantibodies, which are present in almost all patients who have small-cell lung carcinoma and, less often, in patients with other cancers.³⁶ In sections of human brain, spinal cord, or dorsal root ganglia, anti-Hu antibody-containing serum stains the nuclei, but not the nucleoli, of the neurons. Immunoblots of extracts from human neuronal nuclei show that anti-Hu antibodies are directed against a closely spaced group of proteins with a molecular weight of 35–40 kDa.³⁶ Anti-Hu antibodies can be found in higher titers in the CSF, suggesting intrathecal synthesis.

The antigens of the Hu protein are present not only in the tumors of patients with PSN but also in small-cell lung cancer from patients without anti-Hu antibodies or neurologic disease. Further, low titers of anti-Hu antibodies can be seen in up to 20% of patients with small-cell lung cancer without neurologic symptoms, suggesting that PSN may be the result of an autoimmune reaction against antigens shared by both the tumor cells and the dorsal root ganglionic neurons. Although the role of anti-Hu antibodies in the causation of PSN is unclear, these antibodies appear to be highly specific as markers to detect an occult small-cell lung cancer in patients who present with sensory ataxic neuropathy.

AUTOIMMUNE AUTONOMIC NEUROPATHIES

Autoimmune autonomic neuropathy (AAN) is a recently recognized entity highlighted by circulating antibodies against the ganglionic nicotinic acetylcholine receptors (AChR).³⁷ These patients present with a subacute (within 4 weeks) or chronic (within months) onset of neurogenic orthostatic hypotension, defined as a systolic blood pressure reduction of at least 30 mmHg or mean blood pressure reduction of at least 20 mmHg that occurs within 3 minutes of head tilting. The subacute onset is often preceded by a viral infection. In addition, patients demonstrate three or four parasympathetic/enteric symptoms: sicca (dry eyes and dry mouth); abnormal pupillary response to light; upper gastrointestinal symptoms (early satiety, postprandial nausea and vomiting that lead to severe weight loss); and neurogenic bladder. Plasma norepinephrine values are reduced. Patients with more severe cholinergic impairment have higher-titer antibodies against ganglionic AChR, suggesting that these antibodies may be pathogenic.

The pathogenic role of these antibodies was further supported by the observation that some symptoms can be passively transferred to mice injected with the patient's IgG. Further, rabbits immunized with a fragment of ganglionic AChR protein exhibit autonomic failure, similar to that noted in patients with subacute and chronic AAN.³⁸ Because ganglionic AChR have also been found in small-cell lung carcinoma cell lines, cancer may be a potential initiator of ganglionic AChR autoimmunity. AChR antibodies may therefore be implicated in the pathogenesis of diverse neurological disorders, especially paraneoplastic syndromes.³⁸

LOCALIZED, ISOLATED VASCULITIS OF THE PERIPHERAL NERVES

Polyneuropathy is a common manifestation of systemic vasculitis.³⁹ It occurs in patients with polyarteritis nodosa; vasculitis associated with connective tissue diseases, such as rheumatoid arthritis, Sjögren's syndrome, or systemic lupus erythematosus; hypersensitivity vasculitis; or temporal arteritis, in which it may occur up to 14% of cases. There is, however, a distinct vasculitic entity localized only to the peripheral nerve,³⁹ known as isolated peripheral nerve vasculitis (PNV).

PNV involves the small and medium-sized arteries of the epineurium and perineurium and causes ischemic changes within the peripheral nerve. The presentation is similar to that of the vasculitic neuropathy seen in patients with systemic vasculitis – the only difference is the lack of systemic organ involvement. The diagnosis is confirmed with nerve biopsy either of the sural, the superficial peroneal, or the superficial radial nerve. When nerve biopsy is combined with a muscle biopsy, the diagnostic yield is higher. PNV has a better prognosis than the systemic vasculitides and is a treatable form of neuropathy.

An evaluation for PNV should include all the tests needed to exclude systemic vasculitis and cryoglobulinemia, including hepatitis B and C infection, which is often associated with vasculitis of the peripheral nerve.

NEUROPATHY WITH VIRUSES AND HIV

Neuropathy can be seen in a setting of infectious, viral, or bacterial processes. In patients with Lyme disease, various neuropathies, including Guillain-Barré syndrome and mononeuritis (Bell's palsy), have been noted. Other infections, such as CMV, hepatitis, herpes, leprosy, Chagas' disease and diphtheria, can affect peripheral nerves, triggering an autoimmune peripheral neuropathy.

HIV-RELATED PERIPHERAL NEUROPATHIES

The most common neuropathies seen today in a setting of a viral infection are those associated with HIV.

Peripheral neuropathies usually develop in a stage-specific fashion in HIV-infected adults.⁴⁰ Two immune neuropathies, GBS and CIDP, may occur early in the infection, or they may be the presenting manifestation of unsuspected HIV infection. The only difference between HIV-negative GBS or CIDP and the HIV-associated condition is that in the latter there is often pleocytosis in the spinal fluid. Sural nerve biopsy shows segmental demyelination associated with a large number of macrophages within the endoneurial parenchyma. Perivascular inflammation can be also seen. Less common peripheral neuropathies that may develop in early-stage HIV infection include acute ganglioneuritis coincident with seroconversion, and mononeuritis multiplex.

The most common neuropathy in AIDS patients occurs in the later stage of the infection. This is a painful sensory axonal neuropathy that may affect up to 70% of adults with AIDS. Pathologic studies at autopsy indicate that peripheral nerve pathology is ubiquitous in AIDS patients, whether or not they had clinical evidence of peripheral neuropathy. Painful axonal neuropathy can also complicate therapy with the nucleoside analogues ddI or ddC, and may represent the cumulative effect on the peripheral nerves of various endogenous or exogenous neurotoxins related to a multisystem disease and dysfunction of many organs and toxicity to mitochondria. Despite the relative lack of motor involvement, severe neuropathic pain in such patients can be disabling. Pain may be so severe that even contact with light stimuli (e.g., bed sheets) is intolerable. Clinical findings include distal paresthesia or loss of sensation, areflexia, and, in advanced cases, distal weakness.

Another neuropathy seen in later-stage HIV infection is a lumbosacral polyradiculoneuropathy that affects roots and sensory ganglia, often related to CMV infection. CMV polyradiculoneuropathy presents with lower-extremity muscle weakness, sacral and distal paresthesias, areflexia, and atrophy, mostly of the legs, associated with sphincteric dysfunction resembling a cauda equina syndrome. The spinal fluid may show pleocytosis or harbor CMV detected by culture or cytologic examination. CMV inclusions are often found within Schwann cells or endothelial cells (Fig. 66.8). The disease is thought to represent reactivated CMV infection of the nerve root rather than primary infection. Recognition is important because anti-CMV therapy with ganciclovir or foscarnet is helpful.

Although zidovudine (AZT) is myotoxic, the two other antiretroviral drugs, ddC and ddI, are neurotoxic, causing a dose-dependent and reversible axonal painful sensory neuropathy.⁴¹ The major feature that distinguishes a ddI- or ddC-related painful neuropathy from the painful sensory axonal neuropathy of AIDS is that the latter tends to be progressive, whereas the nucleoside-related peripheral

Fig. 66.8 Cross-section of a root from a patient with HIV-associated Guillain-Barré syndrome shows cytomegalovirus inclusions within the Schwann cell.

neuropathies tend to improve when the drugs are discontinued. Another clinical feature of nucleoside neuropathy is 'coasting,' or worsening of symptoms for a period after the drug is discontinued, followed by clinical improvement. The cause of ddC neuropathy is dysfunction of the nerve's mitochondria, which leads to depletion of mitochondrial DNA.⁴¹

PATHOGENESIS OF PERIPHERAL NEUROPATHIES IN HIV INFECTION

The possible mechanisms include direct viral infection, immune alterations triggered by the viral illness, complications of antiretroviral therapy, sequelae of chronic illness, and a combination of all these.

HIV has been cultured from peripheral nerves, and the author has amplified HIV viral RNA from sural nerve biopsy sections in two patients. However, there is no convincing evidence that the neuropathy results from direct infection of peripheral nerves with the virus. The author's own immunocytochemical studies using double-binding techniques on sural nerve biopsies have shown that HIV is present only in rare endoneurial macrophages, but not within the Schwann cells or the axons. With immunocytochemistry, the endoneurial infiltrates in sural nerve biopsies from such patients consist mostly of macrophages; CD8 and CD4 T cells are sparse. There is also strong expression of HLA class I and class II molecules on Schwann cells, endothelial cells, and/or macrophages, as shown in serial sections (Fig. 66.9). The macrophages express co-stimulatory molecules and may behave as antigen-presenting cells.¹⁶ It is possible that systemic viral infection or rare HIV-infected endoneurial lymphoid cells may release lymphokines and cytokines that expose new nerve antigens against which there is no self-tolerance, generating a tissue-specific autoimmune attack. Proliferating macrophages may play a major role as immune effector cells or as sensitized cytotoxic cells responsible for a macrophage-mediated demyelination, similar to that described previously for the Guillain-Barré syndrome in HIV-negative patients. The frequency of anti-myelin or GM1-specific autoantibodies in the

Fig. 66.9 Serial sections of a new biopsy from a patient with HIV-chronic inflammatory demyelinating polyneuropathy stained for (A) HLA-DR, (B) macrophages, and (C) CD8 T shows that the majority of the endoneurial cells are macrophages. Only rare CD8⁺ cells are noted.

serum of these patients is also similar to that in HIV-negative patients with demyelinating polyneuropathies.

TREATMENT

APN are clinically important because they comprise potentially treatable disorders amenable to various immunosuppressive, immunomodulating, or chemotherapeutic agents. The selection of an effective protocol is based on the results of experimental therapeutic trials, clinical experience, and the risk-benefit ratio of available therapies. The author's approach to the treatment of these disorders is described below.

HLA-DR,
Macrophages,
CD8(+)T cells

GUILLAIN-BARRÉ SYNDROME

Supportive care

The dramatic reduction in the mortality of GBS is mainly due to the availability of ICUs, improvement of respiratory support, antibiotic therapy, and control of autonomic cardiac dysregulation. A GBS patient is best monitored in ICU, even if respiratory compromise is not evident at the time of admission. When forced vital capacity (FVC) drops or bulbar weakness is severe, intubation is in order. A team approach provides the best results.

Plasmapheresis

In several double-blind studies⁴² plasmapheresis has been shown to be effective if performed early in the course of the illness. A continuous-flow machine is preferable and a central venous catheter may be required for some patients. Based on two controlled studies, plasma exchange should begin within the first week from onset to be effective. A series of five or six exchanges, with one exchange every other day, is sufficient. Early relapses can occur in up to 20% of patients, who may require a second series of plasma exchanges to abort the relapse. Plasmapheresis has been shown to be effective even in mild cases of GBS; two exchanges are sufficient for mild GBS and four are optimal for moderate cases, but there is no difference between those who receive four plasma exchanges and those who receive six.

High-dose intravenous immunoglobulin

On the basis of two controlled studies using intravenous immunoglobulin (IVIG) versus plasmapheresis,⁴³ IVIG, given at 2 g/kg over 2–5 days, has been shown to be equally effective as plasmapheresis, with no added benefit when the two procedures are combined. The decision as to which treatment to use first, plasmapheresis or IVIG, is governed by circumstances, availability of the treatment modality, experience, age of the patient, and other associated conditions. Early relapses can also occur with IVIG, as often as with plasmapheresis. Because IVIG is easy to administer and more readily available, and because time to initiate treatment is of the essence, IVIG has become the therapeutic choice worldwide.

Steroids are ineffective in GBS and may even increase the incidence of future relapses. A new study combining IVIG with IV methylprednisolone showed a marginal added benefit, but this was not statistically significant.⁴⁴

CIDP

Prednisone

CIDP is a classically steroid-responsive polyneuropathy. The efficacy of steroids was proven in a controlled study. A high-dose regimen of 80–100 mg prednisone daily is begun, and then tapered to every other day.¹³ The starting dose can be a little lower and the tapering faster in patients with coexisting cardiac disease or severe osteoporosis, or the elderly. The goal is to increase strength, and strength is the single parameter to follow. Azathioprine, cyclosporine, or mycophenolate can be used as steroid-sparing agents.

IVIG

In several controlled studies⁴⁵ IVIG has been effective in the majority of patients with CIDP. The more chronic the disease and the more severe the axonal degeneration that has taken place, the fewer the chances that the recovery will be complete or significant. IVIG can be used effectively as a first-line therapy to avoid steroid-related side effects.

Plasmapheresis

Plasmapheresis has been also effective in controlled studies.⁴⁶ After a series of six plasma exchanges, maintenance therapy, with one exchange at least every 8 weeks, may be required if this therapy is beneficial. IVIG has now replaced plasmapheresis, although in the author's experience some patients may benefit more from steroids, others more from IVIG, and still others more after plasmapheresis.

POLYNEUROPATHY WITH PARAPROTEINEMIAS

Patients with benign IgG or IgA demyelinating polyneuropathies respond like CIDP patients. Patients with malignant paraproteinemia should be treated with chemotherapy as needed for the underlying disease. Often the neuropathy responds to chemotherapy. When the neuropathy is axonal, treatments are generally disappointing.

For the IgM anti-MAG demyelinating polyneuropathies, the treatments that have been used are prednisone plus chlorambucil, plasmapheresis, and IVIG,⁴⁷ but the benefit from these therapies has been marginal. Recent studies using rituximab, a monoclonal antibody against CD20, appear promising.⁴⁸ A double-blind study conducted by the author involving 27 patients has now been completed and the results are analyzed.

MULTIFOCAL MOTOR NEUROPATHY

This neuropathy responds very well to IVIG, which is the treatment of choice based on controlled trials. In difficult cases, aggressive treatment with cyclophosphamide followed by plasmapheresis and then IVIG has also been shown to be of benefit in the author's experience. Rituximab is also promising in difficult cases, but no controlled study has been carried out.⁵

PARANEOPLASTIC NEUROPATHY

Anecdotally, some of these patients have responded to plasma exchange or IVIG, but overall this neuropathy is not easily responding to available therapies.

VASCULITIC NEUROPATHIES

Patients with isolated peripheral nerve vasculitis are treated less aggressively than those with systemic vasculitis. A combination of prednisone 1.5 mg/kg/day, and oral cyclophosphamide 2 mg/kg/day, is the treatment

of choice. Although treatment may vary between patients, the administration of cyclophosphamide may not be necessary for more than 12 months as in systemic vasculitis. Often 6–12 months of treatment may suffice. Plasmapheresis has been tried in cryoglobulinemic neuropathies, with variable results.

HIV NEUROPATHIES

The demyelinating neuropathies GBS and CIDP are treated with the same immunomodulatory therapies as used in HIV-negative patients. In uncontrolled studies, plasmapheresis and IVIG have each been effective. The author's preference is IVIG, because it augments rather than suppresses immune function, and it is easily administered.

Ganciclovir appears to be effective in CMV-related polyradiculoneuropathy. Painful sensory neuropathy can be quite disabling because of intractable pain, even though muscle weakness may be minimal. Tricyclic antidepressants, nonsteroidal anti-inflammatory drugs, anticonvulsants (carbamazepine, gabapentin), narcotic analgesics and topical capsaicin in various combinations provide some relief from neuropathic pain, although symptomatic management of this condition is a notoriously difficult clinical problem.

ACKNOWLEDGMENTS

The author thanks the various Neurology Fellows in the Neuromuscular Diseases Section who provided excellent care to his patients; and Drs Amjad Ilyas and Richard Quarles for help with immunochemistry.

Immunologic renal diseases

James E. Balow, Monique E. Cho, Howard A. Austin III

67

Immunologic renal diseases encompass a broad range of clinicopathologic entities, some of which are limited to kidney disease (primary) whereas in others the kidney involvement is one component of a systemic disease (secondary). The immune mechanisms underlying these diverse conditions are equally complex and diverse.¹ This chapter considers the more common immune-mediated diseases of native kidneys, but not those involving immune mediated diseases of renal allografts.

Collectively, immune-mediated kidney diseases represent the third most common cause of end-stage renal failure (after diabetic and hypertensive nephropathies). Disappointingly large numbers of patients first present for medical attention in advanced renal insufficiency. Several factors contribute to the late diagnosis and treatment of immune-mediated kidney disease. Patients with primary glomerular diseases tend to experience few symptoms that prompt them to seek medical evaluation. Shortcomings in the medical system also contribute to late diagnosis and treatment: subtle abnormalities in urinary screening tests are too commonly overlooked or misattributed to inconsequential intercurrent conditions. It is clear from both experimental and clinical studies that early detection is one of the most important determinants of the success of treatment in both primary and secondary forms of immune-mediated renal disorders.

Appropriate evaluation of patients with immune-mediated kidney diseases requires particular attention to the findings of urinalysis, tests of renal functions, and renal biopsy.² Urinalysis plays a pivotal role in the assessment of urinary disorders. The physician should be mindful of the many 'false negative' urinalyses reported by practice-oriented clinical pathology laboratories with high throughput. As a general rule, reports of positive findings are much more likely to be accurate than are negative reports. The thorough clinician should personally review microscopic urinalysis in any case in which there is a reasonable index of suspicion of immune-mediated renal disease.

HEMATURIA

Evaluation of hematuria should begin with determination of whether the bleeding is due to upper urinary tract (glomerular and/or tubulointerstitial) pathology or to lower urinary tract abnormalities. Urinary erythrocyte morphology helps to determine the cause of hematuria. Red blood cells that emanate from lesions of the calices, ureters, bladder or urethra tend

to maintain their normal morphology; when nondysmorphic red blood cells are present, it is usually appropriate to refer the patient to urology for further evaluation. Red blood cells that result from glomerular or tubulointerstitial pathology are more likely to appear dysmorphic (abnormal shapes and sizes, fragmented); when dysmorphic red blood cells are present, it is usually appropriate to refer the patient to nephrology for further evaluation. Erythrocyte and/or leukocyte casts are indicative of glomerulonephritis (or interstitial nephritis). Cellular casts can be formed from erythrocytes and/or leukocytes that enter the tubular lumen because of glomerular or tubular inflammation (Fig. 67.1).

PROTEINURIA

Proteinuria is a cardinal feature of renal parenchymal disease and may indicate glomerular or tubular pathology. Glomerular proteinuria results from a loss of the size-selective and/or charge-selective properties of the glomerular capillary wall and disruptions of the glomerular epithelial cells (podocytes), allowing plasma proteins (especially albumin) to leak into the filtrate. Tubulointerstitial nephropathy often leads to impaired tubular absorption of other normally filtered low molecular weight proteins; this so-called 'tubular proteinuria' exhibits a characteristic pattern on urine protein electrophoresis (low fraction of albumin), rarely exceeds 2 g/day, and is often associated with other manifestations of tubular dysfunction.

The validity of 24-hour urine collections for determination of quantitative proteinuria is often an issue; under- and over-collections are common and must be countered with explicit instructions to patients regarding urine collection. Owing to the high prevalence of collection errors, many clinicians have turned to estimates of proteinuria based on the protein-to-creatinine concentration ratio in random urine samples. Normally, the urine protein-to-creatinine ratio is less than 0.1. This random urine sample method has continued to gain favor as an efficient, cost-effective method to monitor proteinuria in both children and adults.

Filtration of abnormal plasma proteins may be responsible for proteinuria (e.g., multiple myeloma or immunoglobulin light-chain disease). This type of proteinuria (paraproteinuria) may be undetected or underestimated by the dipstick method of evaluation. Abnormal immunoglobulin

Fig. 67.1 Red blood cell cast. Cast present in situ within the lumen of a distal renal tubule. (PAS stain.)

light-chain excretion may be detected by urine protein electrophoresis, but immunofixation electrophoresis is particularly important for detection and definitive diagnosis of paraproteinuria.

NEPHROTIC SYNDROME

The nephrotic syndrome is characterized by substantial degrees of proteinuria (> 3.5 g/day) resulting in hypoalbuminemia, edema, hyperlipidemia and lipiduria. The degree of proteinuria may offer a helpful diagnostic clue because some immune-mediated conditions with typically diffuse glomerular disease (e.g., membranous nephropathy, systemic lupus, amyloidosis) are more likely than others with typically focal disease (e.g., IgA nephropathy, microscopic polyangiitis, Wegener's granulomatosis) to be associated with the nephrotic syndrome.

ACUTE NEPHRITIC SYNDROME

The acute nephritic syndrome is characterized by hematuria (dysmorphic cells), erythrocyte casts, abnormal proteinuria, fluid retention, azotemia and hypertension. Histologically, this constellation of clinical findings is due to proliferative glomerulonephritis. A variant of this syndrome, called rapidly progressive glomerulonephritis, is defined by 50% or greater loss of glomerular filtration rate over 3 months, along with cellular crescents on renal biopsy. It is important to recognize that rapidly progressive glomerulonephritis may present subtly as hematuria and/or proteinuria without oliguria, edema, hypertension or azotemia, yet become an explosive manifestation of several immunologic renal diseases, particularly Wegener's granulomatosis, microscopic polyangiitis, Henoch-Schönlein nephritis, and proliferative lupus nephritis.

CHRONIC GLOMERULONEPHRITIS

Chronic glomerulonephritis is not a diagnosis, but rather is a stage in the evolution of immune-mediated renal disease. The urinalysis often provides valuable clues regarding the duration of glomerular disease. Broad and waxy casts are features of chronic renal disease that are not likely to be seen in recent-onset acute glomerulonephritis.

Table 67.1 Indications for renal biopsy

1. Active 'nephritic' urine sediment
Dysmorphic erythrocytes: > 10 per high-power field
Cellular casts: erythrocyte or leukocyte
2. Proteinuria >2 g/day
3. Abnormal renal function
Associated with the above features of active nephritis
Particularly important if the duration of renal disease and/or rate of change are unknown
4. Document indications for use of high risk therapeutic interventions

Fig. 67.2 Normal glomerular architecture. Note the thin, delicate capillary walls. Neither cells nor matrix encroach upon the patency of the capillary lumina. (PAS stain.)

RENAL BIOPSY

After extensive clinical and laboratory evaluations, a renal biopsy may be indicated to establish or confirm a tissue diagnosis, to clarify the precise type of renal involvement, to formulate a prognosis, and to direct therapy. Some of the more important indications for renal biopsy are listed in Table 67.1. To assist the reader in recognizing patterns of glomerular diseases addressed in subsequent discussions, a normal glomerulus is illustrated in Figure 67.2. An excellent color atlas of glomerular diseases is available.³

MINIMAL CHANGE NEPHROPATHY (LIPOID NEPHROSIS)

Nephrotic syndrome of childhood is mainly due to minimal change nephropathy.⁴ Minimal change nephropathy is an uncommon cause of nephrotic syndrome in neonates and infants, where genetic conditions should receive first consideration. The frequency of minimal change

nephropathy in adults with nephrotic syndrome is low compared to other entities discussed below, but this disease has been seen even into the ninth decade of life.

CLINICAL FEATURES

Minimal change nephropathy characteristically presents with a rather precipitous onset of severe nephrotic syndrome in the absence of signs of a systemic disease. Massive generalized edema and ascites can be very debilitating; these features may be difficult to control with diuretics because of the typically extreme hypoalbuminemia. There are no specific tests short of kidney biopsy to establish a diagnosis of minimal change nephropathy; standard immunologic screening tests are usually normal.

ETIOLOGY AND PATHOGENESIS

The cause of minimal change nephropathy is largely unknown, but this entity is inferentially considered an immune-mediated kidney disease because of its association with some allergic reactions and its characteristic response to immunosuppressive drugs. Reactions to nonsteroidal anti-inflammatory drugs have been invoked in some cases of minimal change nephropathy. Rare cases have been associated with systemic interferon (IFN) treatment, but interestingly not with interleukin (IL)-2. Lymphatic malignancies, particularly Hodgkin's lymphoma, have occasionally been associated with minimal change nephropathy.

The basic lesion of minimal change nephropathy is loss or neutralization of the normal high density of anionic proteoglycans in the glomerular capillary loops. Dissipation of the negative charge barrier allows anionically charged albumin to pass freely. The pathogenic factors that are responsible for massive proteinuria remain elusive. Interdigitating foot processes normally joined by intercellular bridges, called slit diaphragms, form a second barrier to the passage of protein into the urinary space. Characteristically, the podocyte foot processes and slit diaphragms are also disrupted in minimal change nephropathy, although there is uncertainty as to whether these changes are the cause or effect of proteinuria. Recently, mutations of one or more components of the proteins constituting the slit pore complex have been recognized. Recognition of several genetic forms of nephrotic syndrome has led some clinicians to challenge the traditional practice of administering an empiric trial of steroid therapy based on a presumptive diagnosis of classic minimal change nephropathy prior to establishing a specific pathologic diagnosis by renal biopsy and potentially obviating the risk of empiric immunosuppressive therapy.

PATHOLOGY

On light microscopy the renal biopsy is essentially normal, including glomerular tuft cellularity and capillary wall thickness. The characteristic pathologic lesion is seen by electron microscopy where there is fusion of the foot processes of the epithelial cells (podocytes) diffusely around glomerular capillaries. No deposits of antibody or complement components are typically seen.

TREATMENT

Minimal change nephropathy is characteristically exquisitely sensitive to glucocorticoids (remitting within the first few weeks of therapy in over 90% of children). The response rate to glucocorticoids in adults is

KEY CONCEPTS

MINIMAL CHANGE NEPHROPATHY

- >> Most common cause of nephrotic syndrome in children
- >> High rate of response to glucocorticoids
- >> Cyclophosphamide is useful for frequent relapsers
- >> Renal prognosis is excellent
- >> Subset may evolve to focal segmental glomerulosclerosis

somewhat lower and more delayed than in children. A substantial portion of patients with minimal change nephropathy face long-term difficulties with the disease and its therapy: some are steroid-resistant from the start; others are steroid-dependent for control of nephrotic syndrome; still others become frequent relapsers and suffer substantial steroid toxicity with repeated treatments. Controlled trials have shown that alkylating agents (cyclophosphamide or chlorambucil) increase response rates, but in particular reduce rates of relapse. Cyclosporine and mycophenolate mofetil have also been shown to be promising alternatives to prolonged and repeated courses of steroid therapy.

The risk of progression to end-stage renal failure is extremely low in true minimal change nephropathy. However, there is a relationship between minimal change nephropathy and focal segmental glomerulosclerosis, the latter being typically more refractory to therapy and having a much more adverse renal prognosis. Renal biopsy sampling errors account for a mistaken diagnosis of minimal change disease in a proportion of cases that are in fact focal segmental glomerulosclerosis. It is also debated whether a subset of minimal change nephropathy can progress to focal segmental glomerulosclerosis.

FOCAL SEGMENTAL GLOMERULOSCLEROSIS

Few clinical features distinguish patients with new-onset idiopathic nephrotic syndrome due to minimal change nephropathy and focal segmental glomerulosclerosis (FSGS). Patients with FSGS have a higher frequency of microscopic hematuria, higher frequency of persistent nephrotic syndrome, a poorer response to immunosuppressive drug therapies, and a higher risk of progression to end-stage renal failure.⁵ The incidence of FSGS is clearly increasing as a cause of nephrotic syndrome, particularly among black patients, in whom the search for genetic factors is ongoing.

ETIOLOGY AND PATHOGENESIS

The etiology and pathogenesis of FSGS are largely unknown. Evidence that there are multiple forms of FSGS further complicates our understanding of this entity. Studies of alterations in podocyte structures and functions are the central focus of research attempting to elucidate the pathogenesis of various subsets of FSGS. The characteristic renal pathology includes segmental areas of podocyte damage and detachment, irregular foot process fusion, and collapse of glomerular capillaries

Fig. 67.3 Focal segmental glomerulosclerosis. Glomerular capillary loops at the lower left are collapsed and obliterated by excessive matrix and connective tissue. (PAS stain.)

associated with marked local increase in matrix and collagen accumulation (Fig. 67.3). Segmental sclerotic areas typically stain with antisera to IgM and C3 (but not IgG or IgA), particularly areas of glomerular tuft hyalinosis (representing trapped plasma constituents), but none of these collections should be considered to represent classic immune complexes.

Although there is consensus that there are several forms of FSGS, classification schemes for the FSGS variants are somewhat arcane and have not been widely adopted in routine clinical practice.⁶ The collapsing variant of FSGS has been associated with viral infections, notably HIV, and follows a particularly aggressive course. Some forms of FSGS, such as those associated with morbid obesity, appear to result from nonimmunologic glomerular hyperfiltration injury. Potential new insights into the pathogenesis of FSGS emanate from the discovery of plasma factors that, *in vitro*, increase the permeability of normal glomerular capillaries to albumin.⁷ Clinical support for the theory of soluble mediator pathogenesis derives from cases of mother–child transfer of FSGS in utero, and from cases in which fulminant recurrence of FSGS occurs shortly after renal transplantation. Albeit controversially, some investigators have found permeability factors in a subset of cases of FSGS; levels of these factors correlate with remissions and exacerbations of nephrotic syndrome in some cases. Finally, recent evidence indicates that some cases of FSGS are familial and result from mutations in constitutive components of the slit diaphragm filtration barrier.⁸

TREATMENT

It is important to consider the possibility of genetic forms of FSGS before beginning immunosuppressive drug therapy. Treatment of genetic and hyperfiltration-induced forms of FSGS is focused mostly on renoprotection with angiotensin antagonists and lipid-lowering agents. The treatment of other forms of primary FSGS is basically similar to that of minimal change nephropathy and includes prednisone, cyclophosphamide, cyclosporine and mycophenolate. Recent controlled trials have shown that cyclosporine is much more effective than prednisone alone in inducing remission of nephrotic syndrome and in preserving renal

KEY CONCEPTS

FOCAL SEGMENTAL GLOMERULOSCLEROSIS

- >> Nephrotic syndrome with progressive renal insufficiency
- >> Glomerular permeability factor in plasma of some cases
- >> Unpredictable responses to glucocorticoids or cyclophosphamide
- >> Cyclosporine effective but relapses common
- >> Moderately high relapse rate in renal allografts

function in patients with steroid-resistant FSGS.⁹ Preliminary studies have suggested some potential benefit of plasma exchange therapy with or without cyclophosphamide in patients with high plasma levels of permeability factors, and in those relapsing after renal transplant. Complete remission of proteinuria is less commonly achieved than in minimal change nephropathy; however, achievement of even partial remission of proteinuria is associated with improved prognosis and is a laudable goal of treatment.

MEMBRANOUS NEPHROPATHY

Membranous nephropathy is identified in approximately 20% of adults who undergo renal biopsy for the nephrotic syndrome. It is a less frequent cause of nephrotic syndrome in children. Primary membranous nephropathy is a diagnosis of exclusion after considering secondary causes such as medication reactions, infections, neoplasms and systemic illnesses.

ETIOLOGY AND PATHOGENESIS

Membranous nephropathy is characterized by subepithelial (epimembranous) immune deposits containing IgG and complement components. The leading hypothesis based on experimental models is that immune complexes are formed *in situ* by the interaction of a pathogenic antibody with an endogenous glomerular antigen or with an antigen that had been ectopically planted in the glomerulus. Detailed reviews of the immunopathogenesis of membranous nephropathy have recently been published.^{10, 11}

CLINICOPATHOLOGIC FEATURES

The majority of patients with membranous nephropathy present with the nephrotic syndrome. Some are discovered by detection of asymptomatic proteinuria on routine urinalysis. Renal biopsy is usually required to establish the diagnosis of membranous nephropathy. In the early stages of the disease, glomeruli may appear normal by light microscopy. In most cases, light microscopy shows uniform thickening of the glomerular capillary walls without endocapillary cell proliferation (Fig. 67.4). Characteristic subepithelial (epimembranous) and/or intramembranous deposits are seen on electron microscopy (Fig. 67.5). Diagnosis of secondary membranous nephropathy depends on concurrent abnormalities in clinical and laboratory data.

Fig. 67.4 Membranous nephropathy. Capillary walls are nearly uniformly thickened but remain widely patent. Cellularity of the glomerulus is normal. (PAS stain.)

NATURAL HISTORY

The clinical course of idiopathic membranous nephropathy is highly variable. On average, about one-quarter of adult patients progress to end-stage renal failure within 10 years. Another quarter experience a spontaneous remission of proteinuria. The majority are likely to have persistent proteinuria and moderately impaired renal function over an extended period of observation. Patients with sustained hyperlipidemia are at risk for premature cardiovascular disease. Reduction of cardiovascular risk may be as important an element in the rationale for treatment as is preserving kidney function.

It is difficult to predict the clinical course of individual patients with membranous nephropathy. Patients with severe nephrotic syndrome, hypertension and azotemia on presentation have been associated with a poor prognosis in several studies. Protracted high-grade nephrotic-range proteinuria is a relatively strong predictor of an adverse renal outcome. On the other hand, complete or partial remission of proteinuria is associated with excellent long-term prognosis.

TREATMENT

Management of patients with membranous nephropathy usually includes diuretics to reduce edema, lipid-lowering drugs (for severe hyperlipidemia), anticoagulant therapy for thromboembolic complications, and antihypertensive agents. Angiotensin antagonists have been shown to have a substantial anti-proteinuric effect. Whereas patients with severe nephrotic syndrome due to membranous nephropathy are often treated with high-dose alternate-day prednisone, it is generally considered that prednisone does not significantly reduce the risk of progression to renal failure. There is evidence that a combination of prednisone and cytotoxic drug therapy is more effective than prednisone alone. Azathioprine has not been widely used for the treatment of membranous nephropathy. Several small, nonrandomized

Fig. 67.5 Membranous nephropathy (ultrastructure). **(A)** Electron micrograph demonstrates heavy, dark-staining immune complex deposits along the outer surface of the glomerular basement membrane and beneath the epithelial foot processes (hence the terms subepithelial or epimembranous deposits). Note the thickening and projections of the gray-staining basement membrane between the electron-dense deposits. **(B)** Ultrastructure of a normal glomerular capillary wall for comparison. (Electron micrographs courtesy of Dr S. Sabnis, Armed Forces Institute of Pathology; Washington, DC.)

studies of the related drug, mycophenolate mofetil, in patients resistant to other immunosuppressive therapies showed encouraging evidence of benefit. The most compelling results from controlled trials have shown that patients with membranous nephropathy treated with alternating monthly courses of pulse methylprednisolone and

chlorambucil or cyclophosphamide were more likely than controls to experience a remission of the nephrotic syndrome and achieve stable renal function.¹²

Several anecdotal series and controlled trials of cyclosporine in membranous nephropathy have suggested a moderate benefit on proteinuria and renal function.¹³ Relapses of proteinuria are common, particularly after a short course of cyclosporine therapy. Preliminary studies suggest that rituximab (which depletes CD20 B lymphocytes) may be a useful alternative for treatment of membranous nephropathy.¹⁴

MEMBRANOPROLIFERATIVE GLOMERULONEPHRITIS

Membranoproliferative glomerulonephritis (MPGN) is a rare condition that is sometimes referred to as mesangiocapillary glomerulonephritis (Fig. 67.6). Besides the presence of pathologic immunoreactants in glomerular sites, the immune-mediated nature of this disease is suggested by the high frequency of persistent hypocomplementemia. It is of interest that both congenital complement deficiencies (e.g., C3 deficiency) and sustained hypocomplementemia induced by nephritic factor autoantibodies or circulating immune complexes have all been associated with MPGN.

PATHOLOGIC VARIANTS

The nomenclature of MPGN includes two main pathological subsets: type I, MPGN with subendothelial deposits (Fig. 67.7A), and type II, MPGN with dense intramembranous deposits (Fig. 67.7B).¹⁵ Although most cases of MPGN are of unknown etiology, studies over the past decade have shown that chronic hepatitis C infection, particularly when accompanied by cryoglobulinemia, accounts for a substantial portion of cases of type I MPGN.

Types I and II idiopathic MPGN are clinically indistinguishable. Typically, asymptomatic hematuria and proteinuria are discovered incidentally. Judging from the chronicity found on initial renal biopsies, MPGN probably goes undetected for long periods in most patients. Although it is characteristically a chronic low-grade nephropathy, some patients experience complicated nephrotic syndrome and even rapidly progressive and crescentic disease phases.

NEPHRITIC FACTORS

Patients with type II MPGN, and to a lesser extent type I, exhibit a complement-activating antibody called nephritic factor.¹⁶ The typical nephritic factor is an IgG autoantibody that binds to the alternative pathway convertase called C3b,Bb. Nephritic factor stabilizes and prolongs the activity of the enzyme by interfering with normal factors controlling the convertase activity. This leads to sustained activation and

KEY CONCEPTS

MEMBRANOUS NEPHROPATHY

- >> Common cause of idiopathic nephrotic syndrome in adults
- >> Several secondary causes: systemic lupus, drugs, chronic hepatitis, certain malignancies
- >> One-quarter of patients have spontaneous remission
- >> One-quarter of patients develop ESRD within a decade
- >> Protracted nephrotic syndrome confers risks of cardiovascular and thromboembolic events
- >> Therapy: steroids, alkylating agents, lipid-lowering drugs, angiotensin antagonists

Fig. 67.6 Membranoproliferative glomerulonephritis (MPGN). Glomerulus exhibits the typical lobulated appearance of this disease. Markedly increased mesangial cells and matrix in all of the lobules. Mesangium extends outward into the capillary loops and forms double contours with the glomerular basement membrane. (PAS stain.)

Fig. 67.7 Membranoproliferative glomerulonephritis (MPGN) ultrastructure. **(A)** Type I MPGN: capillary wall is markedly thickened and contains heavy, dark-staining electron dense immune complexes in the subendothelial space. Mesangium (lighter material) extends into the capillary loop, where it is interposed between the basement membrane and the endothelium; the process gives the appearance of a massively thickened capillary loop on hematoxylin and eosin staining, and the split appearance by PAS and silver stains. **(B)** Type II MPGN (dense intramembranous deposit disease): capillary loops contain smooth, continuous linear dense material within the basement membrane. (Electron micrographs courtesy of Dr S. Sabnis, Armed Forces Institute of Pathology; Washington, DC.)

severe depletion of serum C3 levels, which is a hallmark of MPGN. Whether or how C3 nephritic factor plays a role in the pathogenesis of either form of MPGN is unknown. Interestingly, in type II MPGN there are no immunoglobulin components in the dense intramembranous deposits, although there are heavy linear deposits of C3 complement, possibly indicating an effect of the prolonged C3 activation.

TREATMENT

There is no consensus about the treatment of MPGN. The overwhelming opinion is that no therapy is effective in inducing remission or in protecting against progressive renal failure. Overall, renal survival is approximately 50% at 10 years from diagnosis, although a subset of patients have a rapidly progressive course if they develop superimposed crescentic glomerulonephritis. Alternate-day prednisone is commonly tried in children with MPGN, but no controlled trials are available and the long-term prognosis remains unfavorable. The efficacy of cytotoxic drug therapy, anticoagulants, and anti-platelet drugs are similarly unproven. Both forms of MPGN tend to recur in renal allografts; recurrences of both types of MPGN have a detrimental effect on graft survival.

POSTINFECTIOUS NEPHROPATHIES

An ever-expanding list of infectious agents has been implicated in the pathogenesis of immune-mediated nephropathies.¹⁷ Some are acute and self-limited, but many of the nephritogenic infections are protracted and are associated with circulating immune complexes, cryoglobulins, high-titer rheumatoid factor, and hypocomplementemia.

KEY CONCEPTS

MEMBRANOPROLIFERATIVE GLOMERULONEPHRITIS (MPGN)

- >> Rare form of chronic nephritis mostly discovered as asymptomatic hematuria, variable proteinuria and/or insidious chronic renal insufficiency
- >> Type I MPGN: subendothelial immune complex deposits
- >> Type II MPGN: dense intramembranous deposits (containing C3 complement)
- >> Hypocomplementemia associated with C3 nephritic factor, an autoantibody to C3 convertase of the alternative complement pathway
- >> Response to immunosuppressive drug treatment generally poor
- >> Both types MPGN tend to recur in renal allografts

VIRAL INFECTIONS

HEPATITIS B

Chronic hepatitis B virus (HBV) has been associated with membranous nephropathy, membranoproliferative glomerulonephritis, and polyarteritis nodosa.¹⁸ The available evidence suggests that HBV-associated nephropathy is immune-complex mediated. Nearly all patients with chronic HBV have HBsAg, anti-HBc antibodies and elevated serum aminotransferase levels. Serum C3 and C4 are reduced in some patients.

Hepatitis B-associated nephropathy most frequently presents as nephrotic syndrome accompanied by microscopic hematuria; only rarely is there evidence of renal functional impairment or progressive liver disease on presentation. Renal biopsy most commonly shows membranous nephropathy; membranoproliferative glomerulonephritis is less common in HBV-associated renal disease. Immunofluorescence studies usually show immunoglobulin, C3 and viral antigens, particularly HBsAg and HBeAg. Electron microscopy shows subepithelial and intramembranous deposits, but unlike in idiopathic membranous nephropathy there may also be mesangial and even some subendothelial deposits.

Therapy for hepatitis B renal disease has focused on antiviral drugs, as glucocorticoids and cytotoxic agents may promote viral replication. Currently, the three drugs approved for hepatitis B infection in adults are recombinant human IFN- α , lamivudine and adefovir. IFN- α has been shown to produce remission of both liver and kidney disease. Lamivudine should be used for at least 1 year, and continued for at least 6 months after HBeAg seroconversion. Adefovir has been evaluated as monotherapy for adults with chronic hepatitis B infection and those resistant to lamivudine.

HEPATITIS C

Hepatitis C virus (HCV) is a major cause of both transfusion-associated and sporadic chronic hepatitis. Persistent infection occurs in approximately 50% of patients and may result in chronic active hepatitis, cirrhosis, cryoglobulinemia, and MPGN. The pathogenesis of the renal disease is unknown, but may relate to deposition within glomeruli of immune complexes containing HCV, anti-HCV antibody and virus-related (or unrelated) cryoglobulins.

Treatment of hepatitis C focuses on antiviral drugs.¹⁹ Combination therapy with IFN- α and ribavirin can be effective in reducing viral replication and improving renal and liver disease. Rituximab and plasma exchange are currently under investigation for the treatment of patients with severe refractory cryoglobulin-related renal disease or vasculitis.

HUMAN IMMUNODEFICIENCY VIRUS (HIV)

Patients with the acquired immunodeficiency syndrome (AIDS) develop a wide variety of renal abnormalities, including focal segmental glomerulosclerosis and drug-induced interstitial nephritis.²⁰ Black patients and intravenous drug abusers are more likely to develop an aggressive form of glomerular disease, currently designated HIV-associated nephropathy (HIVAN). HIVAN is characterized by focal segmental glomerulosclerosis (collapsing type) with extensive tubular ectasia and interstitial fibrosis. Treatment with highly active antiretroviral therapies has somewhat ameliorated the otherwise poor renal prognosis of HIVAN, although complications of the drug therapy itself have been observed. The use of standard immunosuppressive drug therapies for HIVAN is controversial.

■ BACTERIAL INFECTIONS ■

POST-STREPTOCOCCAL GLOMERULONEPHRITIS

Post-streptococcal glomerulonephritis is the result of skin or throat infection with nephritogenic strains of group A streptococci. Nephritic syndrome characteristically appears around 2 weeks after the infection. Whereas the role of streptococcal infection in causing the disease is

widely accepted, the demonstration of streptococcal antigens and antibodies in glomeruli has been controversial.

Post-streptococcal glomerulonephritis is characterized by a nephritic syndrome consisting of smoky or rust-colored urine, generalized edema, hypertension, and nephritic urine sediment. Proteinuria is typically mild. Patients have rising titers of anti-streptolysin and depressed C3 levels early in nephritis but normal or minimally depressed C4 levels, indicating activation of the alternative complement pathway.

Complete clinical resolution of nephritis is the rule, and therefore renal biopsy is not usually indicated in children. In adults, biopsy is often necessary for diagnosis. Proliferative glomerulonephritis with polymorphonuclear leukocyte and monocyte infiltration, granular immune deposits of IgG and C3, and dome-shaped electron-dense subepithelial deposits (humps) are characteristic. The prognosis is excellent: almost all children will recover with supportive care. Progressive renal failure accompanied by severe hypertension appears to be more common in adults.

GLOMERULONEPHRITIS ASSOCIATED WITH FOCAL INFECTIONS

Renal disease has been associated with infective endocarditis, infection of artificial vascular devices, and localized chronic abscesses. A variety of organisms have been implicated in the pathogenesis of renal disease, which seems to be immune-complex mediated. Overlap with renal vasculitic diseases is common. Renal biopsy findings in fulminant infections resemble those of acute post-streptococcal glomerulonephritis. In subacute forms (e.g., endocarditis), focal segmental proliferative glomerulonephritis is more common. The course and prognosis are variable. Antibiotic therapy in most cases is associated with improvement in the renal lesions.

SYPHILIS

Nephropathy may occur in both congenital and acquired syphilis. In acquired syphilis the nephropathy usually becomes apparent during the secondary phase of the infection. Most patients present with nephrotic syndrome and have secondary membranous nephropathy on renal biopsy. Patients with concurrently positive syphilis serologies and antinuclear antibodies may have lupus-related rather than syphilis-associated membranous nephropathy. Following the institution of antimicrobial therapy most, but not all, patients with syphilis-associated nephropathy recover.

■ PARASITIC DISEASES ■

SCHISTOSOMIASIS

Schistosomal infections affect millions of patients in tropical countries. Nephropathy usually occurs after the development of the chronic hepatosplenic infection with *Schistosoma mansoni* and is characterized by proteinuria, hypertension and chronic renal failure. Renal biopsy usually demonstrates focal segmental glomerulosclerosis or membranoproliferative glomerulonephritis. Long-standing schistosomiasis rarely produces secondary renal amyloidosis. Treatment of the underlying schistosomiasis or the nephropathy with corticosteroids

and immunosuppressive therapy do not seem to affect the progression of the schistosomiasis-associated nephropathy.

■ IgA NEPHROPATHY ■

Idiopathic IgA nephropathy (also known as Berger's disease) is among the most common forms of glomerular disease in many parts of the world, especially southern Europe, Australia and Asia.²¹ The high frequency of IgA nephropathy in these countries appears partly to reflect widespread routine screening of healthy schoolchildren and military recruits for urinary abnormalities, and frequent use of renal biopsy to evaluate asymptomatic, isolated hematuria. Renal histologic features and aspects of immunopathogenesis are comparable to those of Henoch-Schönlein nephritis.²²

CLINICAL FEATURES

IgA nephropathy may affect patients of all ages, especially children and young adults, with a male preponderance. Unexplained is the fact that IgA nephropathy is rare in black patients. This observation and examples of familial clustering of IgA nephropathy favor an important element of genetic susceptibility. IgA nephropathy may be discovered as asymptomatic microscopic hematuria. Alternatively, patients (especially children) may present with recurrent episodes of macroscopic hematuria that occur within 24–48 hours after an intercurrent infection, usually an upper respiratory or gastrointestinal tract infection. A transient elevation in serum creatinine has been associated with macroscopic hematuria in about one-third of cases. This has been attributed to tubular injury and obstruction caused by intraluminal red blood cell casts. An episode of macroscopic hematuria is occasionally associated with extensive cellular crescent formation, rapidly deteriorating renal function, hypertension and nephrotic syndrome.

KEY CONCEPTS

INFECTIOUS-RELATED NEPHROPATHIES

- >> *Viral*: Hepatitis B – membranous nephropathy; hepatitis C – cryoglobulinemic membranoproliferative glomerulonephritis; HIV – focal segmental glomerulosclerosis (HIV nephropathy)
- >> *Bacterial (mainly gram-positive)*: Nephritogenic streptococcal infections, prosthetic device (shunt) infections, subacute bacterial endocarditis, chronic deep tissue abscesses – mainly diffuse or focal proliferative glomerulonephritis; secondary syphilis – membranous nephropathy
- >> *Parasitic*: Schistosomiasis mansoni (chronic hepatosplenic form) – focal segmental glomerulosclerosis and membranoproliferative glomerulonephritis
- >> Effective control of renal disease in most conditions (except perhaps schistosomiasis) depends on eradication of the organism; immunosuppressive or anti-inflammatory drug therapies are rarely indicated

NATURAL HISTORY

IgA nephropathy typically has a benign renal prognosis. However, it is recognized that at least one-third of patients with IgA nephropathy eventually progress to end-stage kidney failure. Twenty years after apparent disease onset the probability of renal failure is 25%, and the probability of some renal dysfunction is 50%. Hypertension occurs frequently as the disease progresses and forebodes a poor prognosis.

Other clinical features that have been associated with a poor prognosis include older age at apparent disease onset, persistent proteinuria (>1 g/day), and persistent azotemia. On renal biopsy evaluation extensive cellular crescents, endocapillary proliferation, and extension of immune deposits to the peripheral glomerular capillary walls are indicative of severe immune-mediated glomerulonephritis and a poor prognosis. Evidence of irreversible renal parenchymal injury (glomerular sclerosis, interstitial fibrosis and tubular atrophy) also identifies high-risk patients.

TREATMENT

The treatment of progressive IgA nephropathy remains undefined.^{23, 24} Angiotensin antagonists are recommended to achieve blood pressure control, to reduce proteinuria, and to slow the rate of deterioration of renal function. There are conflicting data about the value of fish oil dietary supplements (eicosanoids) in preventing renal progression in patients with IgA nephropathy. The risk-benefit of corticosteroids is unclear, but these agents are generally used in patients with persistent proteinuria >1 g/day despite maximally tolerated angiotensin antagonist therapies. Cytotoxic drugs are indicated in a small subset of patients with crescentic rapidly progressive IgA glomerulonephritis.

■ HENOC-SCHÖNLEIN NEPHRITIS ■

Henoch-Schönlein purpura (HSP) is a generalized vasculitis that usually affects children and typically involves the skin, joints, kidneys and gastrointestinal tract. Classic Henoch-Schönlein disease, manifested as

KEY CONCEPTS

IgA NEPHRITIS

- >> Common cause of asymptomatic microscopic hematuria, recurrent macroscopic hematuria, and/or low-grade proteinuria
- >> Spectrum of disease, including idiopathic IgA nephritis and Henoch-Schönlein purpura nephritis; IgA in skin and renal biopsies
- >> Mostly benign prognosis, especially in children
- >> Patients with progressive renal insufficiency and/or crescentic glomerulonephritis warrant trial of glucocorticoids and/or cytotoxic drug therapy

purpuric rash with features of joint, kidney and/or gastrointestinal involvement, is readily recognized. Characteristic skin and renal biopsy findings may support the diagnosis. Skin biopsies reveal leukocytoclastic vasculitis with granular deposits of IgA along dermal vessels of purpuric and uninvolved skin.

Whereas in most patients the disease remits spontaneously, some patients develop serious renal and/or gastrointestinal complications. Evidence of immune complex causation has prompted recommendations for immunosuppressive treatment of severe Henoch–Schönlein nephritis, but the data are uncontrolled and controversial.

CLINICAL FEATURES

Urinary abnormalities were seen in about one-third of a largely unselected sample of children with Henoch–Schönlein purpura. Microscopic hematuria is detected in nearly all cases of Henoch–Schönlein nephritis, and is accompanied by variable proteinuria in more than 90% of cases. Approximately 40% of patients reported from referral centers had nephrotic-range proteinuria, and in two-thirds of those there were complicating features, including various combinations of hypertension, azotemia, and hypoproteinemia. Renal biopsy findings range from mild mesangial proliferation to crescentic glomerulonephritis. Immune deposits are predominantly mesangial and characteristically contain IgA.

NATURAL HISTORY

Most patients with Henoch–Schönlein nephritis follow a relatively benign clinical course. The probability of maintaining life-supporting renal function is nearly 90% at 10 years. It is debated whether adults are at greater risk for renal failure than children. Patients who present with microscopic hematuria without proteinuria rarely progress to renal failure. Approximately 80% of patients who initially manifest hematuria and proteinuria have normal renal function with little or no urinary abnormality after extended observation; another 10% are likely to progress to renal failure. Patients who present with proteinuria >1 g/day, impaired renal function and hypertension are at considerable risk for end-stage kidney failure. The renal biopsy also provides useful prognostic information. Widespread cellular crescents, interstitial fibrosis and tubular atrophy portend an increased risk of renal failure.²⁵

THERAPY

Decisions regarding the treatment of Henoch–Schönlein nephritis are made difficult by a lack of compelling data from prospective randomized therapeutic trials and by the highly unpredictable nature of this disease. Corticosteroids and cytotoxic drugs should be reserved for the high-risk patients described above. Pulse intravenous methylprednisolone seems to offer additional benefit. Uncontrolled observations also suggest that azathioprine, cyclosporine, plasma exchange, anticoagulants, dipyridamole and urokinase may be useful, but additional studies are needed. Renal transplantation is a reasonable option for patients who progress to terminal renal failure, provided the disease has been in remission for several months preoperatively.

Fig. 67.8 Renal vasculitis showing both glomerular and arteriolar lesions. Small renal vessel shows healing arteritis with proliferation, edema, and fibrosis which severely compromise the lumen. Lesions in the four glomeruli include segmental fibrinoid necrosis (upper right), cellular crescent (lower right) and hyalinized glomerulus (middle left). Tubular atrophy and interstitial fibrosis are prominent. (Masson stain. Micrograph courtesy of Dr S. Sabnis, Armed Forces Institute of Pathology; Washington, DC.)

■ NEPHROPATHIES ASSOCIATED WITH ANTI-NEUTROPHIL CYTOPLASMIC ANTIBODIES (CLASSIC POLYARTERITIS, MICROSCOPIC POLYANGIITIS, WEGENER'S GRANULOMATOSIS, AND IDIOPATHIC NECROTIZING CRESCENTIC GLOMERULONEPHRITIS) ■

Systemic vasculitis is covered in detail in Chapters 58 and 59. This discussion is limited to the renal components of the major vasculitic syndromes.

CLINICAL AND PATHOLOGIC FEATURES

Renal involvement is common in the systemic vasculitides but varies in type and severity. In classic polyarteritis nodosa the vasculitis affects mainly arteries outside the glomerulus, producing ischemia, hypertension, segmental infarctions, and renal failure. In microscopic polyangiitis, Wegener's granulomatosis and renal-limited necrotizing and crescentic glomerulonephritis, the vasculitis occurs mainly within the glomerulus. The glomerular abnormalities are similar among these groups (Fig. 67.8). The lesions are characteristically focal and segmental in distribution, with fibrinoid necrosis and crescent formation but few, if any, immune deposits (some use the term pauci-immune glomerulonephritis). Clinically, rapidly progressive glomerulonephritis is a common manifestation of these renal vasculitides, making early detection of glomerulonephritis critically important in management.

Table 67.2 Prevalence of ANCA in renal vasculitis

Type of renal vasculitis	ANCA test positivity (%)	
	P-ANCA or Anti-MPO	C-ANCA or Anti-PR3
Polyarteritis nodosa	10-20	10-20
Microscopic polyangiitis	50-80	10-20
Wegener's granulomatosis	10-20	80-90
Necrotizing and crescentic GN	50-80	10-20

MPO = myeloperoxidase; PR3 = proteinase 3

KEY CONCEPTS**RENAL VASCULITIS**

- >> Renal vasculitis with glomerular involvement includes microscopic polyangiitis, Wegener's granulomatosis, and necrotizing crescentic glomerulonephritis (renal-limited vasculitis)
- >> Associated with anti-neutrophil cytoplasmic antibodies (ANCA)
- >> Rapidly progressive glomerulonephritis is common; early treatment includes pulse methylprednisolone, cyclophosphamide (possibly adjunctive plasma exchange)
- >> Maintenance therapy: azathioprine, mycophenolate, methotrexate

Another common feature of the renal vasculitides is the presence of autoantibodies to neutrophil cytoplasmic antigens. As shown in Table 67.2, microscopic polyangiitis, Wegener's granulomatosis and idiopathic necrotizing crescentic glomerulonephritis all express anti-neutrophil cytoplasmic antibodies (ANCA), but in somewhat different patterns. There is a strong correlation between the presence of ANCA and glomerular involvement in systemic vasculitis. Recent murine models with anti-myeloperoxidase antibodies have demonstrated the role of ANCA in the pathogenesis of the vasculitic diseases.²⁶

TREATMENT AND PROGNOSIS

Renal vasculitis tends to be severe and fulminant. Even with early diagnosis, approximately one-third of patients will progress to renal failure within 5 years. Relapsing courses are common in patients with microscopic polyangiitis, and particularly Wegener's granulomatosis. Glucocorticoids are important in the early treatment of renal vasculitis, but their efficacy is limited and maintenance should include alternate-day therapy whenever possible.

In patients with severe pulmonary hemorrhage or rapidly progressive glomerulonephritis due to renal vasculitis, pulse methylprednisolone followed by prednisone and daily cyclophosphamide are clearly indicated. Adjunctive plasma exchange is commonly used in cases of aggressive pulmonary–renal syndrome.

Although controversial, some recent experience indicates that intermittent pulse cyclophosphamide may be substituted for daily cyclophosphamide in order to reduce the toxicity of extended therapy in ANCA-associated glomerulonephritis. Wegener's granulomatosis is generally considered an exception, in which case most investigators advocate daily cyclophosphamide for remission induction therapy with conversion to azathioprine, mycophenolate, or methotrexate for maintenance. Cyclosporine has not proved to be an effective alternative to conventional cytotoxic drug therapy, either as primary therapy or in preventing renal relapse following kidney transplantation. Pilot studies of anti-TNF- α therapy have not shown promising results in the treatment of patients with systemic vasculitis.²⁷

■ ANTI-GBM ANTIBODY-MEDIATED NEPHRITIS: GOODPASTURE'S DISEASE ■

Goodpasture's disease is a rare but classic immune-mediated cause of severe pulmonary–renal syndrome.²⁸ Its essential components include pulmonary hemorrhage and rapidly progressive glomerulonephritis, both of which are characteristically (but not universally) fulminant. The cardinal pathogenic factor is autoantibody to a component of type IV collagen present in the capillary basement membranes of the lung and kidney; this IgG factor is called anti-glomerular basement membrane (anti-GBM) antibody because glomerular antigens are normally used for its detection in immunoassays.

The genesis of anti-GBM antibodies in sporadic cases is unknown. Iatrogenic cases have occurred when normal kidneys have been transplanted into patients with hereditary Alport's nephropathy (who lack normal Goodpasture antigen and tolerance thereto); thus, recipients mount an anti-GBM antibody response to the new donor Goodpasture antigen. It appears that anti-GBM antibodies are expressed for a limited duration (weeks to months) in sporadic cases of Goodpasture's disease. This is of little consolation because of the devastating nature of the disease during the height of the pulmonary–renal syndrome. Hence, aggressive treatments with pulse methylprednisolone, cyclophosphamide and plasma exchange are indicated early in the course of Goodpasture's disease. Reversibility of renal disease is unlikely if renal function is substantially impaired or oliguria ensues before treatment is begun. Immunosuppressive treatment is normally continued until the

KEY CONCEPTS

GOODPASTURE'S DISEASE

- >> Circulating anti-GBM antibody
- >> Pulmonary hemorrhage: treated mostly with pulse methylprednisolone
- >> Rapidly progressive glomerulonephritis with cellular crescents and linear deposits of IgG: treated with high-dose steroids, cyclophosphamide, plasma exchange

Fig. 67.9 Goodpasture's disease. Circumferential cellular crescent fills Bowman's capsule and compresses the glomerular tuft. (Silver stain.)

patient has been in sustained clinical remission and anti-GBM titers are minimal or absent for at least 3 months.

LUPUS NEPHRITIS (CHAPTER 51)

Glomerular disease affects the majority of patients with SLE, but lupus nephritis has a wide spectrum of disease expression and outcomes among different patient populations; in particular, lupus nephritis generally exhibits a substantially more ominous prognosis and a poorer response to treatment in black patients than in white patients. Nephritis is a major cause of morbidity and mortality, and accounts for a large portion of all hospital admissions in lupus patients. The majority experience chronic renal disease with remissions and exacerbations. Patients rarely enter permanent remission or achieve complete cure of SLE.

PATHOGENESIS

Several different mechanisms appear to be involved in the pathogenesis of lupus nephritis, resulting in a wide spectrum of renal lesions. Deposition of immune complexes from the circulation into the

kidney appears to be the initiating event in proliferative lupus nephritis; however, only a subset of immune complexes appears to be nephritogenic. DNA and anti-DNA antibodies are known to be concentrated in glomerular deposits in the subendothelial location and are likely to play a central role in the pathogenesis of proliferative lupus nephritis. Unfortunately, there are fewer insights into the pathogenesis of lupus membranous nephropathy with its characteristic epimembranous immune deposits. Although T cells are almost certainly involved in autoantibody production, it is unknown whether they have a direct role in the pathogenesis of lupus nephritis.

CLINICAL FEATURES

Asymptomatic hematuria or proteinuria may be the presenting features, but they often progress to nephritic and/or nephrotic syndromes.²⁹ Nephrotic syndrome is seen in both severe proliferative and membranous forms of lupus nephritis. Hypertension, azotemia, nephritic urine sediment (with hematuria and cellular casts), hypocomplementemia and high anti-dsDNA titers are more commonly found in patients with proliferative lupus nephritis. Rapidly progressive glomerulonephritis is usually associated with the appearance of cellular crescents and may be superimposed on severe proliferative or membranous forms of lupus nephritis.

DIAGNOSIS

Proper evaluation of the urinary sediment is very helpful in assessing and monitoring renal disease activity. Active glomerulonephritis is indicated by hematuria (with dysmorphic erythrocytes) as well as cellular casts. Broad and/or waxy casts indicate long-standing or advanced glomerulonephritis. Serum complement levels (especially C3 and C4) have been found to correlate with activity of glomerular disease on renal biopsy. Falling levels of complement components may indicate a flare of lupus nephritis; other tests (including anti-dsDNA antibodies) are less reliable. Therapeutic decisions should not be based on serologic tests alone, because none of these tests have adequate sensitivity or specificity to justify treatment decisions. Renal biopsy is indicated only if the patient has laboratory evidence of urinary abnormalities.

The former World Health Organization (WHO) classification of renal biopsy in lupus nephritis has recently been revised by an international committee (Figs 67.9–67.12).³⁰ A summary of the histologic features in each class of lupus nephritis can be found in Table 67.3.

TREATMENT

Treatment of mesangial lupus nephritis is usually not indicated unless protein excretion exceeds 2 g/day. However, the distinction between early mesangial lesions that are in transition to more ominous classes from those that reflect mild and stable nephropathy is difficult. Patients with focal or diffuse proliferative glomerulonephritis and a relative paucity of activity and/or chronicity features on renal biopsy may benefit from oral glucocorticoids or monthly pulses of intravenous methylprednisolone. A prolonged course of intravenous cyclophosphamide pulses is more efficacious than pulses of methylprednisolone in patients with severe focal or diffuse proliferative nephritis.³¹ Plasmapheresis does not offer any significant advantage over cytotoxic therapy. Controlled studies have shown that intermittent

pulse cyclophosphamide is more efficacious than either high-dose conventional prednisone or extended courses of pulse methylprednisolone.^{32,33} In general, treatment should continue for at least 1 year after remission of renal disease to prevent exacerbations. Recent short-term studies have shown that mycophenolate is equivalent to cyclophosphamide for both induction and maintenance therapy in lupus nephritis.^{34–36}

Neither pulse cyclophosphamide nor mycophenolate is universally effective in the management of lupus nephritis, hence the search for more efficacious alternative treatment regimens, including rituximab, immunosuppression without or with stem cell reconstitution, and immunological co-stimulation inhibitors (e.g., CTLA4-Ig), continues.

No definitive therapeutic guidelines have been established for lupus membranous nephropathy. High-dose alternate-day glucocorticoids,

Fig. 67.10 Classes of the pathology of lupus nephritis (1). **(A)** Class II, mesangial proliferative lupus nephritis. Mesangial areas are expanded by cells and matrix but the peripheral capillary loops remain widely patent. PAS stain. **(B)** Class III, focal lupus nephritis. Solid lesion at the lower right portion of this glomerulus demonstrates segmental fibrinoid necrosis. Note the nuclear fragments (karyorrhexis) in the fibrinous exudate. (Hematoxylin and eosin stain.)

Electron micrograph demonstrates the characteristic mesangial deposits (dark materials interspersed within the centrally located amorphous, gray mesangial matrix) and subendothelial deposits (dark materials extending along the peripheral capillary loops).

KEY CONCEPTS

LUPUS NEPHRITIS

- >> Class II, mesangial: no treatment indicated unless transforms to class III or IV disease
- >> Class III, focal nephritis and class IV, diffuse nephritis: high-dose prednisone for induction with alternate-day maintenance with adjunctive immunosuppressive therapy options of: (a) pulse cyclophosphamide or (b) mycophenolate mofetil; azathioprine may be used as more cost effective maintenance therapy
- >> Membranous nephropathy: alternate-day prednisone with bimonthly pulse cyclophosphamide or low-dose daily cyclosporine

Table 67.3 International Society of Nephrology/Renal Pathology Society 2004 Classification of Lupus Nephritis

Class	Histologic features/comments
I. Minimal mesangial	Normal light microscopy (LM); mesangial deposits by immunofluorescence (IF) and electron microscopy (EM)
II. Mesangial proliferative	Pure mesangial hypercellularity and matrix expansion; <i>IF and EM</i> : mesangial immune deposits
III. Focal	Glomerular capillary obliteration in < 50% of nephrons owing to proliferation or sclerosis; <i>LM</i> : Increased numbers of mesangial, endothelial and/or hematogenous cells. Active inflammatory lesions (karyorrhexis, fibrinoid necrosis, adhesion to Bowman's capsule, cellular crescents, interstitial inflammatory infiltrates). Wire loop lesions. Hyaline thrombi; <i>IF and EM</i> : Mesangial and peripheral capillary loop (subendothelial) immune complex deposits
IV. Diffuse	Qualitatively similar histologic lesions as in class III. Glomerular capillary obliteration involving > 50% of nephrons. Subsets defined as primarily global (class IV-G) or primarily segmental (class IV-S) involvement
V. Membranous	<i>LM</i> : Regular thickening of the peripheral capillary loops of the glomerulus. Mesangial expansion; <i>EM</i> : Subepithelial, intramembranous, mesangial (but no or very rare subendothelial) immune complex deposits
VI. Advanced sclerosis	More than 90% global sclerosis without residual active lesions

cyclophosphamide, and cyclosporine have been used, with mixed results. Preliminary results of a prospective controlled trial indicate that both cyclophosphamide and cyclosporine are more effective than steroids alone in inducing complete remission of proteinuria in lupus membranous nephropathy.³⁷

■ SCLERODERMA (SYSTEMIC SCLEROSIS) (CHAPTER 55) ■

Renal disease occurs in the diffuse form of systemic sclerosis and is a major cause of morbidity and mortality in these patients.³⁸ Patients with early (within the first year of disease onset) renal disease may experience rapidly progressive disease and early death. Acute scleroderma renal crisis

Fig. 67.13 Scleroderma renal crisis. Renal arteriole demonstrates extensive fibrin deposition (dark material) within multiple layers of its wall. The lumen is further compromised by severe swelling and intimal hyperplasia. (Masson trichrome stain.)

is particularly ominous. Proteinuria, urine sediment abnormalities (hematuria or pyuria), hypertension and renal insufficiency are clinical markers of renal disease. Renal disease is more common in the first 5 years of the disease, especially if there is rapid progression of skin disease. A significant decrease in renal function, proteinuria in excess of 500 mg/day, or urinary sediment abnormalities should alert the physician. Plasma renin activity increases with the onset of renal injury, but there is no convincing evidence that the rise precedes the onset of scleroderma renal crisis.

Scleroderma renal crisis is characterized by renin-mediated malignant hypertension, rapid deterioration of renal function, and proteinuria (usually nonnephrotic). The primary pathogenic process appears to be a renal vasculopathy involving predominantly the interlobular arteries and arterioles. Marked intimal thickening with an attendant 'mucoid' appearance, and fibrinoid necrosis in the absence of vasculitis, are common and characteristic of the disease (Fig. 67.13). Immune deposits are rarely observed by fluorescence or electron microscopy studies.

Although a variety of treatments have been proposed for patients with scleroderma, none has been proved to be consistently efficacious. The most significant therapeutic advance in the treatment of renal involvement is the use of angiotensin antagonists, which have dramatically increased the 1-year survival of patients with scleroderma renal crisis. Despite this initial improvement, approximately half will subsequently progress to death or renal failure. Survival of patients undergoing any form of treatment for end-stage renal disease due to scleroderma (hemodialysis, peritoneal dialysis or transplantation) has been poor.

■ SJÖGREN'S SYNDROME (CHAPTER 54) ■

A variety of renal manifestations occur in approximately one-third of patients with primary Sjögren's syndrome, including tubular dysfunction (distal or proximal tubular acidosis, nephrogenic diabetes insipidus), nephrocalcinosis, interstitial nephritis, pseudolymphoma, necrotizing vasculitis and glomerulopathy. Mild, nonspecific glomerular changes are

KEY CONCEPTS

NEPHROPATHIES OF SELECTED CONNECTIVE TISSUE DISEASES

- >> *Scleroderma renal crisis*: Predominantly renal vasculopathy; severe (high renin) hypertension with progressive renal failure – treated with angiotensin-converting enzyme inhibitors or receptor antagonists
- >> *Sjögren's syndrome*: Distal renal tubular acidosis with nephrocalcinosis, interstitial nephritis or pseudolymphoma; glomerulonephritis rare
- >> *Rheumatoid arthritis*: Rare proliferative glomerulonephritis, membranous nephropathy, or necrotizing renal vasculitis

common in patients with Sjögren's syndrome. However, overt primary glomerular disease is rare. Membranous nephropathy and proliferative glomerulonephritis (focal or diffuse, and membranoproliferative) have been reported in primary Sjögren's syndrome. In such cases the possibility of overlap with systemic lupus should be considered.

■ RHEUMATOID ARTHRITIS (CHAPTER 52) ■

Although early studies described a condition called 'rheumatoid glomerulonephritis,' several investigators have questioned whether a specific rheumatoid nephritis does in fact exist. From a clinical standpoint, renal disease due to drugs used for its therapy, or secondary amyloidosis developing as a result of chronic debilitating disease, are more common.

Membranous nephropathy, formerly seen as a complication of gold or D-penicillamine therapy, is rarely seen during the course of the more commonly used contemporary therapies for rheumatoid arthritis. Mesangial glomerulonephritis has been described in several patients with rheumatoid arthritis who had renal biopsy because of hematuria and/or proteinuria. No consistent type of glomerular disease has been seen, suggesting the possible coincident diseases. However, an association between high titers of rheumatoid factor and the occurrence of mesangial nephritis has been described, leading to the hypothesis that the renal lesion represents a functional response of the mesangium to remove IgM rheumatoid factor-IgG complexes. Proliferative glomerulonephritis is extremely rare and may be found in patients with rheumatoid vasculitis.

■ RENAL DISEASES IN DYSPROTEINEMIAS AND PARAPROTEINEMIAS (SEE CHAPTER 78) ■

■ MULTIPLE MYELOMA ■

Multiple myeloma results from a neoplastic proliferation of plasma cells that produce one or more abnormal monoclonal proteins (M-proteins). Abnormal bands of light or heavy chains of immunoglobulin are present

in the urine of 50–70% of patients with myeloma. These paraproteins have a predilection to precipitate in the tubular lumina to produce the so-called cast nephropathy or myeloma kidney. Acute renal failure (precipitated by dehydration or contrast dyes) and chronic renal failure may result from the cast tubulopathy. Distal renal tubular acidosis is also a common manifestation of myeloma protein deposition in renal tubules. Myeloma paraproteins are not detected by urine protein dipstick methods. Urinary protein electrophoresis and immunofixation electrophoresis are critically important for diagnosis.

LIGHT-CHAIN DEPOSITION DISEASE

In this systemic disease, monoclonal immunoglobulin light chains, usually κ type, are commonly deposited in the vessel walls of multiple organs, especially the renal glomeruli. Proteinuria (accompanied by nephrotic syndrome in about 30% of cases), microscopic hematuria, hypertension and progressive renal failure are common. Renal biopsy shows nodular sclerosing glomerulonephritis (Fig. 67.14) similar in light-microscopic appearance to diabetic glomerulosclerosis and amyloidosis. Diagnosis depends on finding monoclonal light chains by immunofluorescence studies of renal biopsy tissue. Treatment with prednisone and alkylating agents may halt or reverse the progression of renal failure. Stem cell transplantation has been successful in advanced cases.³⁹

AMYLOIDOSIS

The glomerular and renal vasculature is a common locus for deposition of amyloid fibrils in patients with systemic amyloidosis. Both immunoglobulin-associated (primary, AL) and protein A-associated (secondary, AA) amyloid have been associated with renal involvement.

Proteinuria (often within the nephrotic range) is the most frequent indicator of renal involvement. Hematuria and hypertension are uncommon. Long-standing amyloidosis is regularly accompanied by autonomic neuropathy and postural hypotension. Glomerular involvement is found in all cases of AA amyloidosis, whereas in AL amyloidosis glomerular disease is present in only half of patients.

Fig. 67.14 Light-chain nephropathy. Glomerulus has the characteristic appearance of an extrinsic deposition disease. The mesangial areas are filled with pale-staining material which produces a lobular pattern and severely compromises the capillary loops. Immunofluorescence studies are needed to distinguish the light-chain deposits from amyloid infiltration. (Silver stain.)

Fig. 67.15 Amyloidosis of the kidney. (A) Glomerulus contains nodules of pale-staining amorphous material distorting and compromising the capillary loops. (Silver stain.) (B) Immunohistochemistry of glomerular amyloid deposits demonstrated by peroxidase-labeled antibody specific for AA proteins. (Immunoperoxidase technique.)

KEY CONCEPTS

RENAL DISEASES ASSOCIATED WITH DYSPROTEINEMIAS AND PARAPROTEINEMIAS

- >> *Multiple myeloma*: Cast nephropathy; distal renal tubular acidosis; AL amyloidosis
- >> *Light-chain disease*: Light chain crystalline deposits along basement membranes
- >> *Amyloidosis*: Glomerular and vascular deposition of characteristic amyloid fibrils
- >> *Cryoglobulinemia*: Occlusive microvascular and glomerular 'thrombi' composed of cryoprecipitable protein

Deposition of amyloid protein is recognized by the characteristic staining with metachromatic dyes such as Congo red, which exhibits birefringence on polarized light microscopy. Involvement is typically generalized and diffuse in distribution, and not associated with any significant cellular proliferation or glomerular inflammation (Fig. 67.15)A. Immunohistochemical staining may be used to define the type of amyloid deposit (Fig. 67.15)B. Amyloid deposits initially involve the mesangium, but with disease progression they extend on to the glomerular capillary surfaces (which become markedly and irregularly thickened); this ultimately results in capillary luminal occlusion, glomerular obliteration, and end-stage renal disease. Amyloid deposits are also found in the intrarenal vasculature, resembling hyaline arteriosclerosis on hematoxylin and eosin-stained sections. Electron microscopic findings of fibrillar material of characteristic morphology confirm the diagnosis.

Treatment of primary AL amyloidosis with cytotoxic agents has generally not resulted in a favorable long-term outcome. However, there are some recent very encouraging reports of salutary effects of aggressive cytotoxic drug therapy followed by stem cell reconstitution.⁴⁰ For patients with secondary amyloidosis control of the underlying diseases may prevent, stabilize or even reverse this process.⁴¹ Colchicine and anti-tumor necrosis factor therapies can prevent deposition of amyloid if started early in familial Mediterranean fever.

CRYOGLOBULINEMIA

Cryoglobulins (immunoglobulins which reversibly precipitate on cooling) are present in the serum of patients with a wide variety of autoimmune, lymphoproliferative and infectious diseases. Cryoglobulinemia with MPGN is commonly associated with chronic hepatitis C.⁴² Essential mixed cryoglobulinemia (ECM) refers to an idiopathic clinical syndrome consisting of recurrent episodes of palpable purpura involving the lower extremities, constitutional symptoms, arthralgias, vasculitis, hepatosplenomegaly, lymphadenopathy, and neuropathy.

Renal complications are common with mixed cryoglobulinemia. A waxing and waning course is characteristic of this disease. Glomerular involvement may develop acutely, particularly after dehydration or exposure to cold, and may be associated with oliguric acute renal failure. Other clinical syndromes may also occur, including nephrotic syndrome, hematuria, renal insufficiency, and chronic or rapidly progressive

Fig. 67.16 Cryoglobulinemic nephropathy. Electron micrograph demonstrates dense material completely filling the glomerular capillary lumina. On light microscopy these capillary 'plugs' have the appearance of microvascular thrombi, but ultrastructural studies show the crystalline structure of immune aggregates, not fibrin tactoids. (Electron micrographs courtesy of Dr S. Sabnis, Armed Forces Institute of Pathology; Washington, DC.)

glomerulonephritis. Deposition of cryoglobulins usually occurs in the glomerular subendothelial space, and these deposits exhibit a unique fibrillar appearance on electron microscopy (Fig. 67.16). The glomerulonephritis is typically membranoproliferative and/or crescentic in nature. Large eosinophilic, PAS-positive intraluminal deposits ('thrombi') are found in more than one-third of patients.

Treatments with combinations of glucocorticoids, cytotoxic drugs, rituximab and plasma exchange have been successful in controlling cryoglobulinemic nephritis. IFN- α has been shown in small, nonrandomized studies to be efficacious even in patients refractory to conventional therapy.⁴³

Inflammation and atherothrombosis

Prediman K. Shah

68

Arterial occlusive disorders include atherosclerosis of native arteries, accelerated atherosclerosis involving vein grafts and arteries of transplanted organs, and restenosis following angioplasty and stenting. Atherosclerotic vascular disease is a leading cause of death and disability throughout the USA and other industrialized nations and consumes enormous fiscal resources. An improved understanding of the pathophysiology of atherosclerosis and thrombosis is likely to lead to improved prevention, diagnosis, and treatment of this common disorder.

Atherosclerosis involves the development of a plaque composed of variable amounts of lipoproteins, extracellular matrix (collagen, proteoglycans, glycosaminoglycans), calcium, vascular smooth-muscle cells, inflammatory cells (chiefly monocyte-derived macrophages, T lymphocytes, mast cells, dendritic cells), and new blood vessels (angiogenesis). A body of evidence now suggests that atherosclerosis represents a chronic inflammatory response to vascular injury caused by a variety of agents that activate or injure endothelium and promote lipoprotein infiltration, retention, and modification, combined with leukocyte retention and activation.¹

KEY CONCEPTS

PATHOPHYSIOLOGY OF ATHEROSCLEROSIS

- >> Atherosclerosis is a chronic immunoinflammatory disease
- >> Immune activation and inflammation are involved in the initiation, progression, and destabilization of atherosclerosis
- >> Most lethal consequences of atherosclerosis result from thrombosis superimposed on a ruptured or eroded atherosclerotic plaque
- >> Plaque composition rather than the luminal stenosis severity is the major determinant of vulnerability to plaque rupture
- >> Plaques that are rupture-prone have a large acellular lipid core, intimal and adventitial inflammation, enhanced plaque neovascularity and hemorrhage, and outward adventitial remodeling

SHEAR STRESS AND ENDOTHELIAL INFLAMMATORY GENE ACTIVATION AT SITES OF PREDILECTION

The sites of predilection for atherosclerosis are characterized by low shear stress, evidence of endothelial activation with expression of proinflammatory genes such as leukocyte adhesion molecules, and increased influx and/or prolonged retention of lipoproteins² (Table 68.1 and Fig. 68.1). Specific arterial sites, such as branches, bifurcations, and curvatures, cause characteristic alterations in the flow of blood, including decreased shear stress and increased turbulence. Changes in flow alter the expression of genes that have elements in their promoter regions that respond to shear stress. For example, the genes for intracellular adhesion molecule-1, platelet-derived growth factor B chain, and tissue factor in endothelial cells have these elements, and their expression is increased by reduced shear stress.³⁻⁶ Rolling and adherence of inflammatory cells (monocytes and T cells) occur at these sites as a result of the upregulation of adhesion molecules on both the endothelium and the leukocytes. At these sites, specific molecules form on the endothelium that are responsible for the adherence, migration, and accumulation of monocytes and T cells. Such adhesion molecules, which act as receptors for glycoconjugates and integrins present on monocytes and T cells, include several selectins, intercellular adhesion molecules (ICAM), and vascular cell adhesion molecules (VCAM).³⁻⁶

Molecules associated with the migration of leukocytes across the endothelium, such as platelet endothelial cell adhesion molecules, act in conjunction with chemoattractant molecules generated by the endothelium, smooth muscle, and monocytes – such as monocyte chemoattractant protein-1 (MCP-1), osteopontin, and modified low-density lipoprotein (LDL) – to attract monocytes and T cells into the artery.²⁻⁶ Chemokines may be involved in the chemotaxis and accumulation of macrophages in fatty streaks.⁷ Activation of monocytes and T cells leads to upregulation of receptors on their surfaces, such as the mucin-like molecules that bind selectins, integrins that bind adhesion molecules of the immunoglobulin superfamily, and receptors that bind chemoattractant molecules.

These ligand–receptor interactions further activate mononuclear cells, induce cell proliferation, and help define and localize the inflammatory response at the site of lesions.

In genetically modified mice that are deficient in apolipoprotein E (and have hypercholesterolemia), ICAM-1 is constitutively increased at lesion-prone sites long before the lesions develop.⁵ In contrast, VCAM-1 is absent in normal mice but is present at the same sites as ICAM-1 in mice with apolipoprotein E deficiency.⁵ Mice that are completely deficient in ICAM-1, P-selectin, CD18, or combinations of these molecules have reduced atherosclerosis in response to lipid feeding. Proteolytic enzymes may cleave adhesion molecules such that in situations of chronic inflammation it may be possible to measure the ‘shed’ molecules in plasma as markers of a sustained inflammatory response to help identify patients at risk for atherosclerosis or other inflammatory diseases.^{8,9}

■ KEY ROLE OF ENDOTHELIAL ACTIVATION/DYSFUNCTION AND INFLAMMATION IN ATHEROGENESIS ■

Several studies have suggested that one of the earliest steps in atherogenesis is endothelial activation or injury/dysfunction with infiltration and retention and modification of atherogenic lipoproteins (predominantly the apo B-containing lipoproteins) in the subendothelial space of the vessel wall (Table 68.2).

Various factors that can contribute to endothelial activation or the development of endothelial injury/dysfunction predisposing to atherosclerosis include risk factors such as elevated and modified LDL/very-low-density lipoprotein (VLDL) cholesterol; reduced high-density lipoprotein (HDL) cholesterol; oxidant stress caused by cigarette

smoking, hypertension, and diabetic mellitus; genetic alterations; elevated plasma homocysteine concentrations; infectious microorganisms such as herpes viruses or *Chlamydia pneumoniae*; estrogen deficiency; and advancing age.¹⁰ Endothelial activation and injury/dysfunction may manifest in: (1) increased adhesiveness of the endothelium to inflammatory cells (leukocytes) or platelets; (2) increased vascular permeability; (3) change from an anti-coagulant to a procoagulant phenotype; (4) change from a vasodilator to a vasoconstrictor phenotype; or (5) change from a growth-inhibiting to a growth-promoting phenotype through elaboration of cytokines.

Abnormal vasomotor function has been one of the best-studied manifestations of endothelial dysfunction in subjects with either established atherosclerosis or in those with risk factors for atherosclerosis. Normal healthy endothelium produces nitric oxide from arginine through the action of a family of enzymes known as nitric oxide synthases.¹⁰ Nitric oxide acts as a local vasodilator by increasing smooth-muscle cell cyclic guanosine monophosphate (GMP) levels while at the same time inhibiting platelet aggregation and smooth-muscle cell proliferation.¹⁰ In the presence of risk factors, a reduced vasodilator response to endothelium-dependent vasodilator stimuli or even paradoxical vasoconstrictor response to such stimuli has been observed in large vessels as well as in the microcirculation, even in the absence of structural abnormalities in the vessel wall.¹⁰ These abnormal vasomotor responses have been attributed to reduced bioavailability of endothelium-derived relaxing factor(s), specifically nitric oxide, due to rapid inactivation of nitric oxide by oxidant stress or excess generation of asymmetric dimethylarginine and/or increased production of vasoconstrictors such as endothelin.¹⁰

One of the major contributors to endothelial injury is LDL cholesterol modified by processes such as oxidation, glycation (in diabetes), aggregation, association with proteoglycans, or incorporation into immune complexes.^{10–12} Oxidized LDL has been shown to be present in the atherosclerotic lesions of both experimental animals as well as in humans. Subendothelial retention of LDL particles results in progressive

Table 68.1 Key steps in atherogenesis highlighting role of inflammation at various steps

1. Endothelial activation with increased infiltration of atherogenic lipoproteins at sites of low or oscillating shear stress (branch points and flow dividers)
2. Subendothelial retention and modification of atherogenic lipoproteins (low-density lipoprotein/very-low-density lipoprotein)
3. Endothelial activation with increased mononuclear leukocyte (inflammatory cell) adhesion, chemotaxis, and subendothelial recruitment
4. Subendothelial inflammatory cell activation with lipid ingestion through monocyte scavenger receptor expression resulting in foam cell formation
5. Intimal migration and proliferation of medial/adventitial smooth-muscle cells/myofibroblasts in response to growth factors released by activated monocytes with matrix production and formation of fibrous cap and fibrous plaque
6. Abluminal plaque growth with positive (outward) arterial adventitial remodeling preserving lumen size in early stages; later, plaque growth or negative remodeling results in luminal narrowing
7. Neoangiogenesis due to angiogenic stimuli produced by inflammatory cells (macrophages) and other arterial wall cells (vascular endothelial growth factor, interleukin-8)
8. Death of foam cells by necrosis/apoptosis leading to necrotic lipid core formation
9. Plaque disruption (rupture of fibrous cap or endothelial erosion) due to inflammatory cell-mediated matrix degradation and death of matrix-synthesizing smooth-muscle cells
10. Exposure of thrombogenic substrate (lipid core-containing tissue factor derived from inflammatory cells) following plaque disruption with arterial thrombosis

Fig. 68.1 Different shear stress patterns, resulting from different flow patterns in the athero-prone segment versus athero-resistant segment of a human carotid artery, as measured by ultrasound technique, are shown. Note that the low shear stress flow pattern in athero-prone segments is able to induce inflammatory genes in endothelial cells in culture; this may contribute to propensity for lesion localization at athero-prone sites. (Adapted from Dai G, Kaazempur-Mofrad MR, Natarajan S, et al. Distinct endothelial phenotypes evoked by arterial waveforms derived from atherosclerosis-susceptible and -resistant regions of human vasculature. *Proc Natl Acad Sci USA* 2004; 101: 14871–14876.)

Table 68.2 Endothelial activation/dysfunction in atherosclerosis**Phenotypic features**

Reduced vasodilator and increased vasoconstrictor capacity
 Enhanced oxidant stress with increased inactivation of nitric oxide
 Increased expression of endothelin
 Enhanced leukocyte (inflammatory cell) adhesion and recruitment
 Increased adhesion molecule expression (ICAM, VCAM)
 Increased chemotactic molecule expression (MCP-1, IL-8)
 Increased prothrombotic and reduced fibrinolytic phenotype
 Increased growth-promoting phenotype

Factors contributing to endothelial activation/dysfunction

Dyslipidemia and atherogenic lipoprotein modification
 Elevated LDL, VLDL, LP(a)
 LDL modification (oxidation, glycation)
 Reduced HDL
 Increased angiotensin II and hypertension
 Insulin resistance and diabetes
 Estrogen deficiency
 Smoking
 Hyperhomocysteinemia
 Advancing age
 Infection?

HDL, high-density lipoprotein; ICAM, intercellular adhesion molecules; IL-8, interleukin-8; LDL, low-density lipoprotein; LP, lipoprotein; MCP-1, monocyte chemoattractant protein-1; VCAM, vascular cell adhesion molecules; VLDL, very-low-density lipoprotein.

oxidation and its subsequent internalization by macrophages through the scavenger receptors. The internalization leads to the formation of lipid peroxides and facilitates the accumulation of cholesterol esters, even finally resulting in the formation of foam cells. Once modified and taken up by macrophages, LDL activates the foam cells. In addition to its ability to injure these cells, modified LDL is chemotactic for other monocytes and can upregulate the expression of genes for macrophage colony-stimulating factor (M-CSF) and monocyte chemoattractant protein derived from endothelial cells.¹³ Thus, it may help expand the inflammatory response by stimulating the replication of monocyte-derived macrophages and the entry of new monocytes into lesions. Continued inflammatory response stimulates migration and proliferation of smooth-muscle cells that accumulate within the areas of inflammation to form an intermediate fibroproliferative lesion resulting in thickening of the artery wall.

The inflammatory and immune response in atherosclerosis consists of accumulation of monocyte-derived macrophages and specific subtypes of T lymphocytes at every stage of the disease.^{14, 15} The fatty streak, the earliest type lesion, common in infants and young children, consists of monocyte-derived macrophages, macrophage-derived foam cells, and T lymphocytes. The critical role of the macrophage in atherogenesis is supported by the virtual absence (or drastic reduction) of atherosclerosis when M-CSF null genotype is introduced in

murine models of severe dyslipidemia induced by diet or genetic manipulation.¹⁶

Continued inflammation results in increased numbers of macrophages and lymphocytes, which both emigrate from the blood and multiply within the lesion. Activation of these cells leads to the release of proteolytic enzymes, cytokines, chemokines, and growth factors, which can induce further damage and eventually lead to focal necrosis. Necrosis and/or apoptosis of foam cells results in the formation of the necrotic lipid core in the plaque. Thus, cycles of accumulation of mononuclear cells, migration and proliferation of smooth-muscle cells, and formation of fibrous tissue lead to further enlargement and restructuring of the lesion, so that it becomes covered by a fibrous cap that overlies a core of lipid and necrotic tissue, resulting in the formation of an advanced and complicated atherosclerotic plaque.

The inflammatory response itself can influence lipoprotein transfer within the vessel wall. Proinflammatory cytokines, such as tumor necrosis factor- α (TNF- α), interleukin-1 (IL-1), and M-CSF increase binding of LDL to endothelium and smooth muscle and increase the transcription of the LDL receptor gene.¹ After binding to scavenger receptors *in vitro*, modified LDL initiates a series of intracellular events that include the induction of proteases and inflammatory cytokines.¹ Thus, a vicious circle of inflammation, modification of lipoproteins, and further inflammation can be maintained in the artery by the presence of these modified lipoproteins.

Monocyte-derived macrophages are present in various stages of atherosclerosis and act as scavenging and antigen-presenting cells. They produce cytokines, chemokines, growth-regulating molecules, tissue factor, metalloproteinases, and other hydrolytic enzymes. The continuing entry, survival, and replication of monocytes/macrophages in lesions depend in part on growth factors, such as M-CSF and granulocyte-macrophage colony-stimulating factor (GM-CSF), whereas IL-2 is involved in a similar manner for T lymphocytes. Recent experimental observations suggest that in and out trafficking of macrophages within the atherosclerotic vascular wall may be regulated by the microenvironment within the lesion with ingress and retention being promoted by a proinflammatory milieu related to oxidized lipids, whereas egress via the lumen or via transformation into migratory dendritic cells and subsequent immigration to regional lymph nodes is associated with reduced proinflammatory lipids in the lesion – an environment promoted by high HDL levels favoring lesion regression.¹⁷ Dendritic cells have been identified within the subendothelium and the adventitia of normal blood vessels. An increase in the number and activity of subendothelial dendritic cells has been observed in the atherosclerotic lesion, raising the possibility that dendritic cells may be involved in the pathophysiology of atherosclerosis.¹⁸

Activated macrophages as well as lesional smooth-muscle cells express class II histocompatibility antigens such as human leukocyte antigen (HLA)-DR that allow them to present antigens to T lymphocytes.^{1, 14, 15} Atherosclerotic lesions contain both CD4 and CD8 T cells, implicating the immune system in atherogenesis.^{14, 15} T-cell activation, following antigen processing, results in production of various cytokines, such as interferon- γ (INF- γ) and TNF- α and β , which can further enhance the inflammatory response.¹ Antigens presented include oxidized LDL and heat shock protein 60 (HSP60), which may participate in the immune response in atherosclerosis.^{2, 14, 15}

Macrophages, T cells, endothelial and smooth-muscle cells in the atherosclerotic lesions express CD40 ligand and its receptor, which may play a role in atherogenesis by regulating the function of inflammatory cells.¹⁹ The anti-atherogenic effects of CD40-blocking antibodies in the murine model of atherosclerosis suggest that CD40-mediated signaling may play an important role in atherogenesis.²⁰

Platelet adhesion and mural thrombosis are ubiquitous in the initiation and generation of the lesions of atherosclerosis in animals and humans.¹ Platelets can adhere to dysfunctional endothelium, exposed collagen, and macrophages. When activated, platelets release their granules, which contain cytokines and growth factors that, together with thrombin, may contribute to the migration and proliferation of smooth-muscle cells and monocytes. Activation of platelets leads to the formation of free arachidonic acid, which can be transformed into prostaglandins such as thromboxane A₂, one of the most potent vasoconstricting and platelet-aggregating substances known, or into leukotrienes, which can amplify the inflammatory response.

Angiotensin II, a potent vasoconstrictor, may also contribute to atherogenesis by stimulating the growth of smooth muscle, increasing oxidant stress, inducing LDL oxidation, and promoting an inflammatory response.^{1, 20–22}

Elevated plasma homocysteine concentrations, resulting from enzymatic defects or vitamin deficiency, may facilitate atherothrombosis by inducing endothelial dysfunction with reduction in vasodilator capacity and enhanced prothrombotic phenotype and smooth-muscle replication.^{23–25} Hyperhomocysteinemia is associated with an increased risk of atherosclerosis of the coronary, peripheral, and cerebral arteries.^{23–25} Recently completed clinical trials have failed to demonstrate clinical cardiovascular benefits from reduction of plasma homocysteine levels by vitamins.²⁵

POTENTIAL ROLE OF INFECTION IN ATHEROTHROMBOSIS

It is likely that a number of stimuli are responsible for provoking and sustaining a chronic inflammatory response in the vessel wall in atherosclerosis. Among the key potential culprits are the modified lipoproteins and infectious agents. Oxidatively modified lipoproteins can induce a variety of proinflammatory genes in the vessel wall that are responsible for recruiting and activating inflammatory cells such as ICAM- and VCAM-type adhesion molecules, chemotactic cytokines such as MCP-1 and IL-8, and colony-stimulating factors such as M-CSF. In addition to modified lipoproteins, there is now a body of evidence suggesting that arterial wall infections with organisms such as *Chlamydia pneumoniae*, cytomegalovirus/herpes virus, as well as remote infections such as chronic bronchitis, gingivitis, and *Helicobacter pylori* infection, may affect inflammation, thereby contributing to atherogenesis and/or plaque disruption and thrombosis in the presence of pre-existing atherosclerosis^{23–31} (Table 68.3). Increased titers of antibodies to these organisms have been used as a predictor of further adverse events in patients who have had a myocardial infarction.

Organisms, particularly *Chlamydia pneumoniae*, have been identified in atheromatous lesions in coronary arteries and in other organs obtained at autopsy. The case for *C. pneumoniae* is of

Immune-mediated vascular injury through molecular mimicry (*Chlamydia pneumoniae*)

Remote infections with systemic activation of the inflammatory response (*Helicobacter pylori*, *Porphyromonas gingivalis*)

particular interest since both in the hypercholesterolemic rabbit as well as in genetically hyperlipidemic mice, acceleration of atherosclerosis with *C. pneumoniae* infection has been demonstrated.³⁰ In addition, pilot clinical trials of anti-chlamydial macrolide antibiotics have raised the possibility that such therapy may reduce the risk of recurrent coronary events.^{31, 32} *In vitro* studies have suggested that *C. pneumoniae* can trigger proatherogenic events, such as foam cell formation, procoagulant activity, and metalloproteinase activity in monocytes, probably mediated by its HSP60. Molecular antigenic mimicry between certain *Chlamydia* antigens and myosin has also raised the additional possibility that such antigenic mimicry could be involved in an immune-mediated vascular and myocardial injury. However, recent large-scale clinical trials have failed to demonstrate any clinical benefit of using antibiotics targeting *C. pneumoniae*, raising questions about the link between infection and atherothrombosis.^{33–36}

TOLL-LIKE RECEPTORS, INNATE IMMUNITY AND ATHEROSCLEROSIS

Toll-like receptors (TLR) are a family of transmembrane receptors that serve as signaling receptors in the innate immune system; their ligation by exogenous and possibly endogenous ligands triggers a proinflammatory signaling cascade in various cells linking innate immunity to inflammation³⁷ (Chapter 3). Recent studies have shown that TLRs are expressed in murine and human atherosclerotic lesions and that hyperlipidemia induces proinflammatory signaling, in part through these receptors and their downstream adaptor molecules such as MyD88 (myeloid differentiation factor) contributing to vascular inflammation, neointimal hyperplasia, and atherosclerosis in murine models.^{38, 39}

ANGIOGENESIS IN ATHEROSCLEROSIS

Angiogenesis or neovascularization is an essential process that supports chronic inflammation and fibroproliferation, processes that are involved in atherogenesis. Several studies have demonstrated increased neoangiogenesis in atherosclerotic lesions and hypercholesterolemia has been shown to increase adventitial neovascularity in porcine arteries before the development of an atherosclerotic lesion.⁴⁰ Proinflammatory chemokines such as IL-8 and other angiogenic growth factors such as vascular endothelial growth factor (VEGF) have been demonstrated in atherosclerotic lesions where they could contribute to angiogenesis. Angiogenesis may contribute to plaque progression by providing a source of intraplaque hemorrhage that in turn may provide red cell membrane-derived cholesterol, contributing to the expansion of the necrotic lipid core. In addition neovascular channels may also provide a source of inflammatory cells into the vessel wall; thus angiogenesis and inflammation appear to be linked pathophysiologic processes.⁴¹ The ability of macrophages to undergo transdifferentiation into functional endothelial cells has been demonstrated, suggesting a more direct link between inflammation and angiogenesis.⁴² Preliminary data demonstrating an inhibitory effect of angiostatin in murine models of atherosclerosis suggest the potential proatherogenic role for angiogenesis.⁴³

ROLE OF INFLAMMATION IN PLAQUE RUPTURE, PLAQUE EROSION, AND THROMBOSIS

Thrombosis complicating atherosclerosis is the mechanism by which atherosclerosis leads to acute ischemic syndromes of unstable angina, non-Q- and Q-wave myocardial infarction and many cases of sudden cardiac death.⁴⁴⁻⁴⁶ In most cases, coronary thrombosis occurs as a result of uneven thinning and rupture of the fibrous cap, often at the shoulders of a lipid-rich lesion where macrophages and T cells enter, accumulate, and are activated, and where apoptosis may occur⁴⁴⁻⁴⁶ (Figs 68.2-68.4)). Thinning of the fibrous cap may result from elaboration of matrix-degrading metalloproteinases (MMPs) such as collagenases (MMP-1, MMP-13), gelatinases (MMP-2, MMP-9), elastases (MMP-12), and stromelysins (MMP-3), and/or other proteases such as cathepsins, by inflammatory cells, chiefly macrophages.⁴⁴⁻⁴⁸ These proteases may be induced or activated by oxidized LDL, cell-to-cell interaction between macrophages and activated T cells, CD40 ligation, mast cell-derived proteases, oxidant radicals, matrix proteins such as tenascin-C, and infectious agents.⁴⁴⁻⁴⁸ Thinning can also result from increased smooth-muscle cell death by apoptosis/necrosis and consequent reduced matrix production; increased smooth-muscle cell death may result from oxidized LDL, cleavage products of tenascin-c or by direct contact with plaque-infiltrating CD4 T cells expressing TNF-related apoptosis-inducing ligand (TRAIL).⁴⁹⁻⁵¹

Inflammatory cells, specifically the macrophages, are also the main source of tissue factor in the atherosclerotic plaque.⁵² Tissue factor, when exposed to circulating blood, interacts with activated factor VII to generate activated factor X; activated factor X in turn cleaves thrombin from prothrombin. Thrombin is involved in recruiting and activating platelets as well as the clotting cascade, thereby initiating thrombus formation. Tissue factor

expression is increased in atherosclerotic plaques, particularly in unstable coronary syndromes.⁵² The lipid core of the atheromatous lesion is heavily impregnated with tissue factor derived from dead (possibly apoptotic) macrophages and foam cells, accounting for its high thrombogenicity. Macrophage tissue factor expression may be induced by a variety of signals in the atherosclerotic plaque, including various cytokines, infectious agents, and oxidized

Fig. 68.4 Coronary thrombosis resulting from superficial endothelial erosion without rupture of the plaque (plaque erosion).

THERAPEUTIC PRINCIPLES

MANAGEMENT OF ATHEROTHROMBOSIS

- >> Atherothrombotic clinical events can be reduced or prevented by:
 - >> prevention of progression of atherosclerosis
 - >> stabilization of lesions by changing plaque composition
 - >> facilitating regression of pre-existing lesions
- >> Traditional risk factor modification, including low-density lipoprotein lowering, reduces atherothrombotic events largely by slowing or preventing lesion progression or by lesion stabilization through change in lesion composition (reduced plaque lipid and plaque inflammation)
- >> Increasing quantity or functional quality of high-density lipoprotein can regress atherosclerotic lesions and reduce plaque inflammation by promoting egress of plaque lipid and inflammatory cells
- >> Direct immune modulation to suppress proinflammatory aspects or to stimulate anti-inflammatory aspects of the immune system can also inhibit atherothrombosis

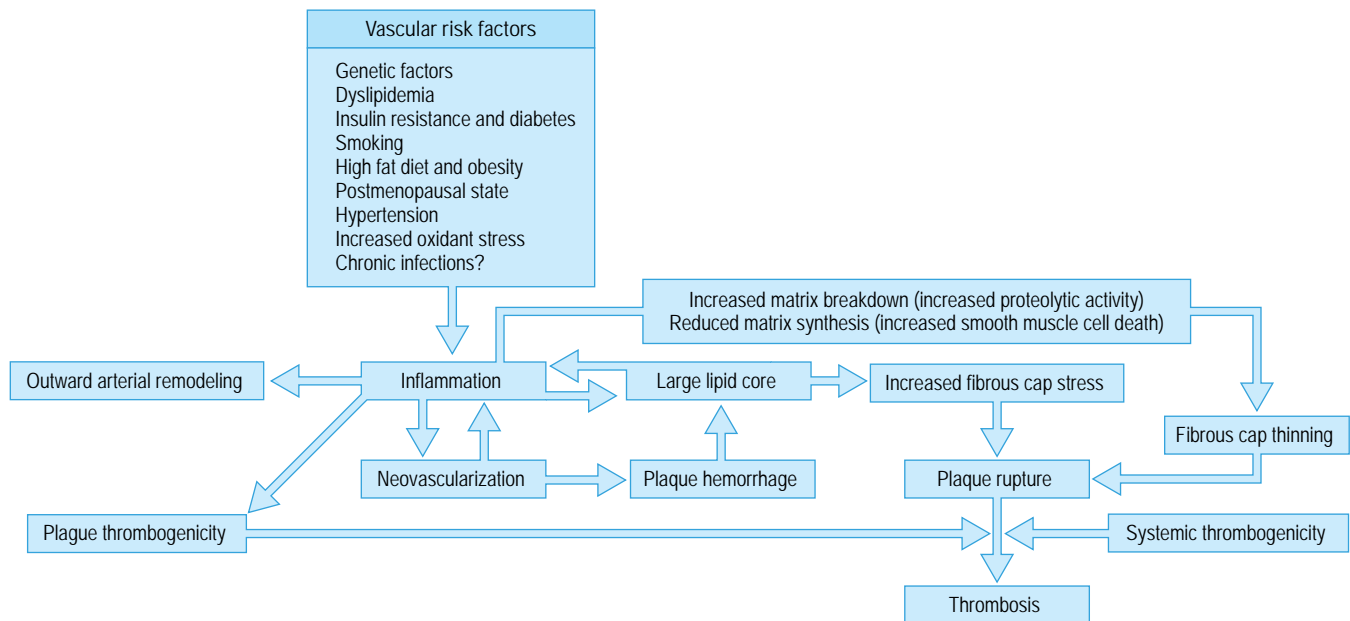

Fig. 68.5 Scheme showing the pathophysiology of plaque rupture and thrombosis.

lipoproteins. Thrombosis may also occur on a proteoglycan-rich matrix without a large lipid core, and in such cases, evidence of superficial endothelial erosion is found.⁵³ This plaque erosion may account for thrombosis in a relatively higher proportion of young victims of sudden death, particularly in women and smokers.⁵⁴ The precise molecular basis for these plaque erosions

is not clear, although endothelial desquamation through activation of basement membrane-degrading MMP may be involved.⁴⁸

Plaques with a large core, active inflammatory infiltration, and a thinned fibrous cap are therefore considered vulnerable or unstable plaques. Their identification can be particularly difficult because they

may not produce symptoms due to lack of flow-limiting stenoses and may thus escape detection by stress testing and even angiography. Inflammation in atherosclerosis may be accompanied by elevation of circulating proinflammatory markers such as C-reactive protein (CRP), IL-6, serum amyloid A, and a variety of soluble leukocyte adhesion molecules.^{54–56} Elevated CRP levels predict an increased risk of adverse cardiac events in patients with symptomatic vascular disease as well as in asymptomatic subjects at risk for vascular disease.⁵⁴

CONCLUSIONS

Atherosclerosis is a complex disease process that involves lipoprotein influx, lipoprotein modification, increased pro-oxidant stress, and inflammatory, angiogenic, and fibroproliferative responses intermingled with extracellular matrix and lipid accumulation, resulting in the formation of an atherosclerotic plaque. Endothelial activation/dysfunction is common in atherosclerosis and often manifests as a reduced vasodilator or enhanced vasoconstrictor phenotype that contributes to luminal compromise. Thrombosis resulting from plaque rupture or superficial erosion complicates atherosclerosis, often resulting in abrupt luminal occlusion with resultant acute ischemic syndromes (Fig. 68.5). Infectious agents may contribute to the inflammatory response and thus to destabilization of lesions. An improved understanding of the pathophysiology of atherosclerosis is providing novel directions for its prevention and treatment. In particular, the recognition of the important role of inflammation could lead to novel therapeutic interventions directed at selective inhibition of inflammatory cascade in the vessel wall. Targeting inflammatory triggers such as lipoproteins, angiotensin II, possible infectious agents, and others is likely to lead to improved outcomes in patients with atherosclerosis.

Autoimmune thyroid diseases

Su He Wang, James R. Baker Jr.

69

Autoimmune thyroid disease (AITD) is the most common organ-specific autoimmune disorder. AITD includes a group of thyroid diseases that share the common finding of altered thyroid function, with susceptibility determined by a combination of genetic and environmental factors. The pathogenesis of AITD is associated with autoimmune responses against specific components of thyroid tissues, including cell membrane proteins, receptors, and enzymes. AITD affects 1–2% of the population, and is 5–10-fold more common in women. AITD is generally divided into two entities: autoimmune hyperthyroidism and autoimmune thyroiditis. The details of these disorders are listed in Table 69.1.

The concept of autoimmune responses to thyroid antigens originated more than 50 years ago when antithyroid antibodies were found in the serum of patients with Hashimoto's thyroiditis (HT), followed by the induction of experimental autoimmune thyroiditis in animals.¹ Subsequently, the long-acting thyroid stimulator (LATS) was discovered to be an immunoglobulin that caused Graves' disease (GD).² We continue to progress in our ability to understand the pathogenesis of AITD, and especially of GD and HT, the two most common thyroid disorders.

■ GRAVES' DISEASE ■

GD accounts for most cases of hyperthyroidism. It is named after the Irish physician Robert J. Graves, who first gave a clinical description of the disease in 1835, although the symptoms of hyperthyroidism were noted in the early 1800s. It was 51 years after Graves' description, however, that excessive production of thyroid hormones was proposed as the cause of the disease. After several decades' active study of hyperthyroid-related hormones, in 1956 Adams and Purves discovered an abnormal thyroid stimulator protein named LATS in the serum of patients with GD.² The nature of LATS was later identified as an autoantibody against thyroid follicular cell thyrotropin receptors, and since that time GD has been classified as an autoimmune disease.

GENETIC AND ENVIRONMENTAL FACTORS

GD is a common disorder in the general population, with an incidence of 1–1.5 cases/1000 population. The etiology is largely unknown; however, development of the disease appears predominantly in genetically susceptible individuals. Family members of a patient with GD are more likely than would be expected by chance to have AITD or other organ-specific autoimmune diseases. Studies on monozygotic twins have indicated that the disease has a concordance rate of only 30–60%.³ Another study of 8966 pairs of twins showed that 35% of monozygotic twins (versus 3% of dizygotic twins) were concordant for GD.⁴ The result provides a measure of the relative contribution of genetic as opposed to environmental factors to disease susceptibility. It is estimated that up to 79% of the predisposition to GD is the result of genetic factors.⁴ However, the expression of GD in genetically susceptible individuals is certainly regulated by environmental agents and endogenous factors in either permissive or protective ways.

One of the most significant pathological features seen in GD is an infiltrate of activated lymphocytes in the thyroid gland, which exhibit increased expression of major histocompatibility complex (MHC) class II molecules. MHC genes and their products play a crucial role in determining immune responses, particularly through antigen presentation (Chapter 5). There is overwhelming evidence that loci in the human leukocyte antigen (HLA) region (chromosome 6p21) are important, providing a relative risk of 1.9–4.0 for GD.⁵ An association between GD and HLA-DR3 in Caucasian populations has been noted, although this might not be the case in other races.⁶ Other studies indicate that HLA-DR3 is in strong linkage disequilibrium with DQB1*0201 and DQA1*0501, both of which are strongly associated with GD.⁷ HLA-DQB1*0303 has been suggested to be a race-specific susceptible allele for GD in Hong Kong Chinese.⁶ Two HLA-DRB1 alleles might contribute independently to GD susceptibility.⁸ Within the crystal structure of HLA-DRB1, residues characteristic of alleles that are positively and negatively associated with GD have been identified. There are also reports indicating no significant linkage between MHC genes and GD.⁹ The HLA locus did not co-segregate with disease in DR3-positive

families,¹⁰ suggesting that HLA genes may not be the major genes for AITD expression, even within DR3-positive families. However, considering that HLA-DR3 was associated with GD in the probands,⁷ it is most likely that the DR3 gene is a modulating gene that contributes to the effect of other susceptibility genes. Nevertheless, the above data suggest that controversy exists on the actual role of HLA in the development of GD.

Several non-MHC genes may also be linked to the pathogenesis of GD (Table 69.2). These genes include the cytotoxic T lymphocyte antigen-4 (CTLA-4) gene, the thyroid-stimulating hormone receptor (TSHR) gene, GD-1, an X-chromosome gene, vitamin D receptor (VDR), CD40, interferon (IFN)- γ , interleukin-4 (IL-4), IL-1 receptor antagonist (IL-1RA) gene, and the lymphoid protein tyrosine phosphatase (PTPN22). CTLA-4, located on chromosome 2q33, plays an important role in the regulation of T-cell activation (Chapter 13). The linkage between the CTLA-4 gene and GD has been found in different races and geographical locations.²² Primary susceptibility has now been mapped to CTLA-4 itself, with an odds ratio of 1.5 (confidence interval (CI), 1.31–1.75; $P=2.72 \times 10^{-8}$) for GD.²² CTLA-4 gene polymorphisms are also thought to be linked to thyroid autoantibody production,¹² suggesting a broad role of CTLA-4 in immune modulation, as opposed to being specific for GD. In some GD pedigrees, CTLA-4 polymorphisms synergistically enhanced the risk conferred by MHC alleles. CTLA-4 splice variants may regulate immunoregulatory pathways that

are essential (but not sufficient) for autoimmunity in both mice and humans.²²

Many cytokine gene polymorphisms have been examined among patients with GD. A significant reduction in the frequency of the variant T allele of the IL-4 promoter (C/T single nucleotide polymorphism (SNP); position -590) was found in GD.¹⁶ However, other studies have failed to support this finding.²³ One case-control study reported that the frequency of an allele for the IL-1RA gene was significantly increased in patients with GD.¹⁵ However, similar to IL-4, the result has been difficult to replicate.²⁴ In addition to IL-4 and IL-1RA, there is an important association between IFN- γ microsatellite polymorphisms and GD.¹⁴ However, it is likely that these microsatellite polymorphisms play only a minor role in the susceptibility to GD. A genome-wide screen in GD has suggested the presence of a major GD susceptibility gene on chromosome 20q11.2,²⁵ designated GD-2. Subsequently, the gene encoding CD40, which stimulates lymphocyte proliferation and differentiation, was mapped to this region, and a C/T polymorphism in the 5' untranslated region of the CD40 was associated with the susceptibility to and the phenotype of GD.¹¹ Several reports have indicated that VDR polymorphisms are associated with GD.²⁰ However, VDR polymorphism analysis needs to be stratified according to the population background.²⁰ The gene encoding lymphoid PTPN22 may be a general susceptibility locus for several autoimmune diseases, including GD.¹⁸ It is proposed that autoimmune-associated lymphoid tyrosine phosphatase is a gain-of-function variant.¹⁹

Several studies have failed to show any significant role of the TSHR gene locus in the genetics of GD.²⁶ GD-1, a locus located on chromosome 14q31, has been suggested as being a major GD-susceptible gene,²⁷ and this location is close to the multinodular goiter-1 locus. An unknown gene(s) located on the X-chromosome at Xq21.33-22 has also been linked to GD.²¹ Considering that GD is a female-predominant disease, this preliminary result is very interesting.

In summary, GD appears to be a polygenic disorder in which each gene contributes a certain amount to an individual's susceptibility. Although a number of susceptible genes have been associated with GD, their relative contributions to pathogenesis have yet to be clearly defined. Moreover, additional nongenetic factors significantly contribute to the etiology of this disorder.

Both human and animal studies have indicated that chronic excess iodine supplementation may modulate the expression of AITD in genetically susceptible individuals. Iodine can stimulate B lymphocytes to increase immunoglobulin production, enhance T-lymphocyte activity, and influence the expression of MHC antigens. Although excess iodine is unlikely to cause GD *de novo* in normal subjects, recurrence is almost certainly affected by iodine intake. Patients given iodine supplementation after discontinuing treatment with antithyroid drugs are more likely to relapse than those who do not receive iodine. GD is more likely to recur in areas of high iodine intake than in areas of normal iodine intake following thyroidectomy.²⁸ Comparable doses of antithyroid drugs are more likely to cause hypothyroidism in patients with GD who reside in an area of iodine deficiency than in those residing in an area of iodine sufficiency.²⁹

Studies have implicated stress in changing thyroid function by increasing uptake of iodine and stimulating secretion of TSH and thyroid hormones.³⁰ The incidence of GD is significantly increased in populations exposed to major wars.³⁰ While there is strong evidence that stress is related to the development of GD, it is unlikely that, in and of itself, it can induce the disease.

X-chromosome at Xq21.33-22	21

CLINICAL PEARLS

SUSPECTED ENVIRONMENTAL RISK FACTORS IN GRAVES' DISEASE

Clinical/epidemiological phenomenon observed

Increased incidence or recurrent rate in high iodine intake areas
Increased incidence in populations exposed to war
Female predominance
Occurrence after viral or bacterial infections

Pathogenic factors suggested

Excess iodine
Stress
Female hormones
Infections

KEY CONCEPTS

IMMUNOLOGIC FEATURES IN GRAVES' DISEASE

- >> Presence of autoantibodies, particularly thyroid-stimulating hormone-stimulating antibodies (TSAb)
- >> Infiltration of T cells into the thyroid parenchyma, mostly CD4 T cells
- >> Thyroid expression of major histocompatibility complex (MHC) class II antigens, especially human leukocyte antigen (HLA)-DR antigen
- >> Recognition of thyroid antigens by T cells

There is increasing evidence showing a connection between infectious agents and GD. Many studies suggest that GD often occurs after infection. The frequency of antibodies to *Yersinia enterocolitica*, a Gram-negative bacillus, is significantly increased in patients with GD. Furthermore, *Y. enterocolitica* appears to have saturable TSH-binding sites³¹; this bacillus may contain antigenic determinants that cross-react with human thyroid autoantigens. Other microorganisms may also be predisposing agents in GD by breaking tolerance to autoantigens, stimulating cytokine production, changing host cell components, and through molecular mimicry (Chapter 50).

PATHOGENESIS

An immune response is initiated when T-cell receptors recognize foreign peptides or self-peptide fragments bound to HLA molecules. HLA class II molecules are usually only expressed on antigen-presenting cells, such as B cells, dendritic cells, and macrophages, and not on epithelial cells such as thyrocytes. As mentioned above, several HLA molecules encoded by the class II gene region have been reported to be associated with GD. Abnormal or aberrant expression of these antigens on thyrocytes and lymphocytes may play a key role in the development of GD.

GD is characterized by lymphocytic infiltration of the thyroid gland. It is believed that T cells and B cells accumulate in the thyroid gland (Fig. 69.1), as a result of various factors such as viral/bacterial infection, stress, sex hormones, and genetic abnormality. Cytokines and other molecules released during initial steps of the disease may upregulate the expression of MHC class I and class II molecules on the surface of thyroid cells, which may become adequate antigen-presenting cells and present TSHR peptides.

Fig. 69.1 Graves' disease, showing epithelial hyperplasia, lymphocytic infiltration and fibrous bands. (Courtesy of Dr. Thomas Giordano, Department of Pathology, University of Michigan.)

Alternatively, infection might produce mimic peptides or alter host cell components such that they could be attacked by the immune system.

Analysis of the phenotypic profile of intrathyroidal T lymphocytes in GD reveals CD4 T-cell dominance; only a few infiltrating T cells are CD8. CD4 T cells are capable of helping locally abundant B cells to produce antibodies. Mechanisms leading to the selection of relevant CD4 T cells in the thyroid tissue remain unclear. The number of intrathyroidal CD4 T cells decreased, whereas CD8 T cells increased in patients treated with antithyroid medicines.

TSHR is the dominating force in regulating thyroid gland growth and differentiation. TSHR can undergo different intramolecular cleavage and/or conformational changes into three functional epitopes or subunits, A, B, and C.³² These three epitopes can function as autoantigens to initiate different pathological reactions. Autoantibodies that bind to epitope A can mimic TSH, causing thyroid stimulation, and thus they are named TSHR-stimulating antibodies (TSAb). By binding to the epitope A on thyroid follicular cells, TSAb stimulate excessive cyclic adenosine monophosphate (cAMP) synthesis and induce excess production of thyroid hormones, leading to hyperthyroidism or GD. Shed epitope A can act as a systemic antigenic stimulus and may contribute to the breakdown of TSHR tolerance in susceptible individuals.³² In healthy individuals, thyroid hormone release is normally regulated by feedback inhibition from TSH, but the presence of TSAb disrupts this system because the generation of TSAb is

independent of thyroid hormones. As a result, the TSHR is under continuing stimulation by TSAb.

Epitope B comprises a small part of the ectodomain and the transmembrane region. Autoantibodies against epitope B can block the thyrotropic action of TSH, causing hypothyroidism.³² Therefore, these autoantibodies are termed TSHR-blocking antibodies (TBAb). Some patients with GD may eventually develop hypothyroidism, not because the thyroid gland itself is destroyed by autoreactive cells, but because the nature of the TSAb generated switches from agonist to antagonist.

Epitope C is a region located in the N-terminus of the TSHR ectodomain cleaved from the holoreceptor. Autoantibodies bind to epitope C but result in no signal transduction. Therefore, these autoantibodies are designed as TSHR-neutral autoantibodies (TNAb). The presence of TNAb has been reported in patients with GD as well as in normal subjects.³² The physiological or pathophysiological relevance of TNAb remains unclear. However, TNAb may inhibit TSHR cleavage and, as a consequence, prolong the half-life of the TSHR.

In addition to autoantibodies against TSHR, other nonspecific autoantibodies against various components of the thyroid gland, including thyroid peroxidase (TPO), thyroid Na/iodine transporter and thyroglobulin, can also be present in GD.

■ PREVENTION AND PATIENT MANAGEMENT ■

There is no effective way of preventing the occurrence of GD. Prior to a confirmatory diagnosis, an effective means of controlling symptoms is the use of inhibitors of β -adrenergic receptors, such as propranolol. These β -adrenergic blocking agents can also be used after diagnosis with other therapies.

Treatment of GD focuses on decreasing the overproduction of thyroid hormones and returning the patient to an euthyroid state. There are three standard methods available for treatment: antithyroid medication, radioactive ablation, and surgical thyroidectomy. Table 69.3 shows the various medications available for the treatment of GD and the sites of their actions. Propylthiouracil and methimazole are the two antithyroid drugs that are most frequently used. They not only inhibit the production of thyroid hormones, relieving hyperthyroidism, but also decrease the size and vascularity of the goiter, making it more amenable to a definitive therapy with surgery or radioactive iodine if necessary. Both radioactive iodine and surgical subtotal thyroidectomy are final, ablative therapies. The destructive therapy with ¹³¹I is beneficial because patients do not relapse, but it may increase the risk of posttreatment orbitopathy or worsening of existing orbitopathy. Corticosteroids, lithium, ipodate, and amiodarone have also been used in the treatment of GD.

One study has reported that combining antithyroid drugs with thyroxine (T_4) initially and then suppressive doses of T_4 alone maintains a continually low level of TSAb and thus prevents the recurrence of hyperthyroidism.³³ However, other groups have been unable to obtain the same result.³⁴

In order to determine the efficiency of therapy, dose of use, and length of maintenance, some pathological markers need to be monitored during the treatment. Among many markers, thyroid hormone and TSH concentrations are perhaps the most useful. The measurement of TSAb levels has also been used to assess the response to treatment and to predict relapse or remission.³²

■ PATIENT EVALUATION AND DIFFERENTIAL DIAGNOSIS ■

GD typically presents with a diffuse goiter and thyrotoxicosis. The classic signs of hyperthyroidism are heat intolerance; hand tremors; nervousness; irritability; warm, moist skin; weight loss; muscle reflex changes; hyperdynamic cardiovascular status with tachycardia; hyperdefecation; and changes in mental status.

Approximately 20–25% of patients who present with clinical thyroid-associated ophthalmopathy are characterized by proptosis. However, subclinical thyroid-associated ophthalmopathy can be found in a majority of patients with GD when more sensitive imaging techniques (computed tomography scan or magnetic resonance imaging) are used. Surprisingly, some patients with clinical thyroid-associated ophthalmopathy can present without any evidence of Graves' hyperthyroidism, though autoantibodies against the thyroid may exist. TSH receptors are known to be expressed in the orbital connective tissues, but the potential role of the TSH receptor has yet to be established. Thyroid-associated dermopathy usually presents as a swelling in the pretibial area (myxedema) and in the feet, face, or hands, and rarely in other parts of the body. Furthermore, dermopathy typically coexists with and sometimes precedes thyroid-associated ophthalmopathy.

Laboratory findings in patients with hyperthyroidism include elevated levels of total and free triiodothyronine (T_3) and T_4 . Because T_4 and T_3 are usually bound to proteins, testing for free T_4 is more accurate because it is the only thyroid hormone that is free to enter tissues.³⁵ TSH levels are low or undetectable because the stimulation of the thyroid gland is exogenous, rather than from the pituitary axis, and the elevated levels of the thyroid hormones cause a feedback inhibition of the pituitary TSH secretion. The appearance of TSAb is regarded as a specific and pathogenic marker for GD. This autoantibody can be demonstrated in about 90% of GD patients. A detectable rate less than 100% is probably due to the insensitive methodology that is currently available, rather than to the absolute absence of TSAb because thyroid glands of GD patients always show an increased uptake of radioactive iodine. Finally, a diffuse homogeneous uptake on a radioisotopic scan of the thyroid is almost pathognomonic of GD.

A differential diagnosis of GD involves exclusion of other thyroid disorders with hyperthyroidism, such as HT, pituitary tumors, or thyroid adenomas. Most of these can be ruled out by determining that the thyroid gland has a diffused increase in iodine uptake. The presence of ophthalmopathy is good diagnostic evidence of GD. Sometimes it is difficult to differentiate between GD and HT. Fine-needle biopsy helps the diagnosis. In HT, the lymphocytic infiltrate is usually diffuse and is considerably more intense than in GD. Oxyphilic cells, typical of HT, are usually absent in GD.

The hypermetabolic state of pregnancy can be confused with GD. Systemic symptoms such as fatigue, heat intolerance, emotional lability, and hyperhidrosis are often part of normal pregnancy. A normal pregnancy may also be associated with a slight increase in the size of the thyroid gland and warm and moist skin. Therefore, these nonspecific symptoms cannot be used in making a diagnosis of hyperthyroidism. However, a failure to gain weight adequately may serve as a useful sign. Laboratory confirmation of the clinical suspicion is essential. Radioisotope tests should be avoided because of the risk to the fetus.

Table 69.3 Therapies available for the treatment of Graves' disease

Beta-blockers	Inhibition of peripheral thyroxine (T_4) conversion to the active hormone triiodothyronine (T_3) Block of sympathetic action
Iodine	Inhibition of thyroid hormone release Inhibition of thyroid-stimulating hormone action on thyroid
Iodate	Inhibition of thyroid hormone synthesis Decrease of serum T_3 and increase of serum rT_3
Lithium	Inhibition of T_4 release
Steroids	Immunosuppressive actions Inhibition of peripheral monodeiodination, causing a decrease in serum T_3 and an increase in serum rT_3
Thionamides	Inhibition of thyroglobin synthesis Correction of abnormal immune responses

HASHIMOTO'S THYROIDITIS

HT was first described by H. Hashimoto in 1912 as struma lymphomatosa. The autoantibodies present in this disorder were identified in 1956 by Roitt et al.^{36, 41} HT is characterized by lymphocytic infiltration of the parenchyma (Fig. 69.2) (causing a dense accumulation of lymphocytes, plasma cells, and macrophages sometimes with germinal center formation) and by the presence of thyroid autoantibodies to thyroglobulin and to TPO. HT is the most common underlying cause for hypothyroidism. It has been estimated that about 3–4% of the population suffers from HT. This disorder is most commonly found in middle-aged and elderly females, but it also occurs in other age groups. HT is distributed throughout the world without racial and ethnic restriction. It occurs more commonly in families where another member has an AITD or another organ-specific autoimmune disease, such as systemic lupus erythematosus.

GENETIC AND ENVIRONMENTAL FACTORS

The etiology of HT is not known, but, similar to GD, it is believed to be an interplay between genetic and environmental factors. The relative contribution of each is not clearly defined and may vary from patient to patient. Thyroid antibodies are found with high frequency among first-degree relatives, and there is a high degree of concordance among twins and triplets. Siblings of adult patients with HT have about a 50% chance of developing thyroid autoantibodies³⁶; however, the mode of inheritance has not been defined. Most of the genetic studies look at the HLA region (Table 69.4). There is increasing evidence to support the association between HT and HLA-DR3.⁴⁰

Studies on both human and animal models have indicated that the autoimmune process in HT is a multistep process (Fig. 69.3). Initially it is believed that the immune system in susceptible individuals is altered by environmental factors. Such alterations in the immune system may result in defective immunoregulatory pathways, such as reduced function of the coinhibitory molecule or in CTLA-4, CD4⁺CD25⁺ T regulatory cells (CD4⁺CD25⁺ Treg cells).⁴⁶ Genetic elements are apparent from the fact that 95% of patients who acquire the disease are women,⁴⁷ strongly suggesting a role for sex hormones in

Fig. 69.2 Hashimoto's thyroiditis, with prominent infiltration by lymphocytes, plasma cells, and oncocytic metaplasia of residual follicular epithelium. (Courtesy of Dr. Thomas Giordano, Department of Pathology, University of Michigan.)

disease. Testosterone suppresses and estrogen exacerbates experimental autoimmune thyroiditis induced by immunization of mice or by thymectomy; castration of male animal increases the severity of experimental autoimmune thyroiditis.⁴⁸ Furthermore, the expression of a functional estrogen receptor in thyroid cells suggests that thyrocytes may be sex-hormone-responsive.⁴⁹ Infection, iodine, and irradiation might also increase the risk of developing HT.

There is increasing evidence that CD4⁺CD25⁺ Treg cells represent an important mechanism for the maintenance of self-tolerance (Chapter 16). Removal of CD4⁺CD25⁺ Treg cells from mice that do not develop autoimmune disease can result in autoimmune thyroiditis. Furthermore, CD4⁺CD25⁺ Treg cells are able to prevent experimental autoimmune thyroiditis.⁴⁶ CD4⁺CD25⁺ Treg cells produce a number of molecules that are known to have immunosuppressive effects, including CD25, IL-2,

CTLA-4, IL-10, GITR, LAG-3, Foxp3, and transforming growth factor- β (TGF- β). It is currently believed that immunosuppressive mechanisms of Treg cells in patients with HT are defective due to intrinsic factors in the thyroid microenvironment. Reduction of several of these molecules may enhance the activity of B cells, which produce autoantibodies against TPO, and thyroglobulin. Depending upon the method of

detection, 55–90% of patients with HT exhibit anti-thyroglobulin antibodies, while 82–91% exhibit anti-TPO antibodies.^{50, 51}

On the other hand, a defect in CD4⁺CD25⁺ Treg cells may promote the production of Th1 cytokines and thus increase the levels of IL-1 β , IFN- γ and tumor necrosis factor- α (TNF- α), all of which are known to play an important role in triggering apoptosis in thyroid cells.^{52, 53} Thyroid follicles are either destroyed or damaged, and therefore their

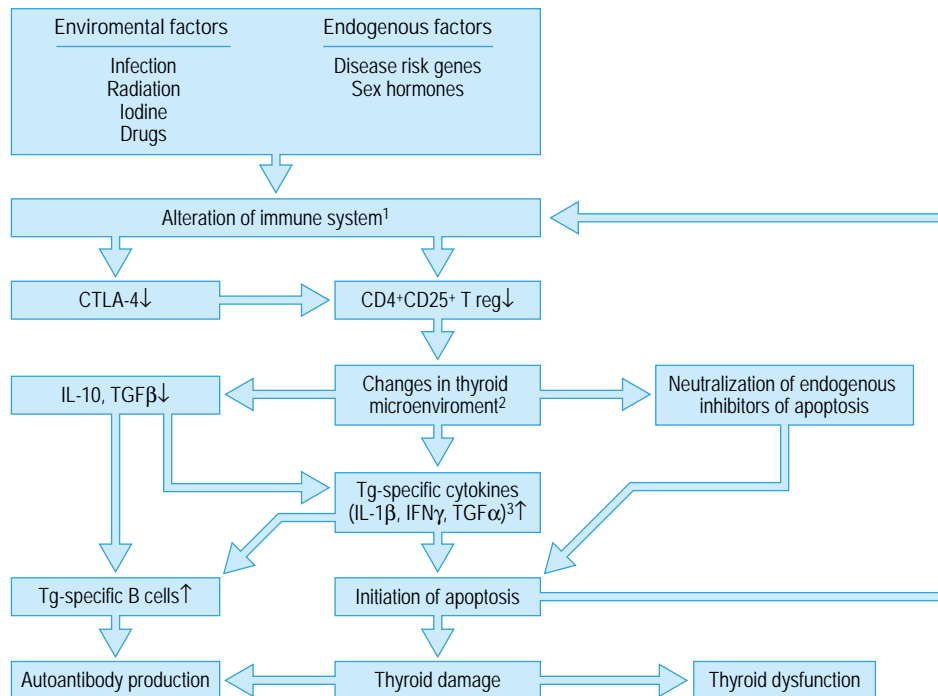

Fig. 69.3 Hashimoto's thyroiditis: pathways of thyroid cell damage. With the influence of environmental factors, the immune system in genetically susceptible individuals loses its surveillance function. A defect in CD4⁺CD25⁺ regulatory T cells occurs, which leads to changes in the thyroid microenvironment. Subsequently, the production of Th1 cytokines is increased and apoptosis inhibition is removed. The thyroid is damaged by apoptosis.

numbers are reduced. Traditionally it has been thought that thyroid follicles are injured by cytotoxicity, but now there is increasing evidence that apoptosis plays a key role in the loss of thyroid cells.⁵²⁻⁵⁴ Figure 69.4 shows that apoptosis occurs in follicular thyroid cells. Thyroid cells are known to express apoptotic molecules, such as TNF, Fas, and TNF-related apoptosis-inducing ligand (TRAIL)⁵⁵ (Chapter 14). The Fas apoptosis pathway is implicated in CD8-T-cell-mediated cytotoxicity. Under physiologic conditions, these apoptotic molecules may remain inactivated. The process of lymphocytic infiltration into an inflamed thyroid can be inhibited by direct injection of a FasL-expression vector,⁵⁶ suggesting that FasL can induce apoptosis of the infiltrating lymphocytes. Although Fas is known to be expressed constitutively on thyrocytes (Fig. 69.5), normally it does not cause apoptosis even in the presence of excess anti-Fas antibodies. The Fas-FasL pathway may therefore be regulated in thyrocytes, and certain combinations of inflammatory cytokines may reverse the inhibition.^{52,53}

PATHOGENESIS

Basement membranes on thyroid follicular cells from HT are shown to stain positive for immune complexes and terminal complement components.⁴¹ In an inflammatory or immunologic response, thyroid cells may express the intercellular adhesion molecules ICAM-1, VCAM-1, and LFA-3. Adhesion molecules have been implicated not only in cell adhesion but also in signal transduction, leading to cellular activation and proliferation. The presence of these adhesion molecules may induce thyroid follicular cells to bind T cells and thus significantly increase thyroid cell damage mediated by cytotoxic T cells. One of the important characteristics of HT is the formation of germinal centers within the thyroid gland. Germinal centers constitute a specialized microenvironment essential for the induction of antibody synthesis, affinity maturation of B cells, memory B-cell formation, and maintenance of T-cell memory. The interactions among thyroid follicular cells, dendritic-like cells, infiltrating B cells, and T cells in germinal centers may have a key role in the generation of thyroid

autoantibodies, the production of cytokines, and the formation of memory B and T cells.

PREVENTION AND PATIENT MANAGEMENT

The cause of HT is largely unknown, and no preventive approaches are available. The treatment usually consists of thyroid hormone replacement for hypothyroidism, which is generally required lifelong. In response to thyroid hormone therapy, levels of antithyroid antibodies often decrease. In patients with symptomatic goiter, thyroid hormones at doses that suppress TSH secretion may decrease the size of the gland. Although immunosuppressive (corticosteroid) therapy may regress thyroid enlargement, it is not recommended because corticosteroids have serious side effects. Patients with coexisting thyrotoxicosis should be treated with antithyroid drugs and should be carefully monitored for levels of thyroid hormones. An appropriate therapy is not available for patients who are euthyroid but have enlarged glands. Thyroid hormone therapy may decrease the size of the gland in some cases and increase it in others.

Occasionally, HT coexists with GD, often presenting with hyperthyroidism. Antithyroid treatment should be handled with extreme caution because patients with both diseases are more likely to become hypothyroid after surgical or radioactive iodine therapy than patients with GD alone.

With recent advances in understanding of how the thyroid is damaged, several experimental therapies have emerged for the treatment of autoimmune thyroiditis. One such new approach is enhancement of the activity of CD4⁺CD25⁺ Treg cells, which has successfully resulted in the suppression of mTg-specific effector T cells and the inhibition of damage in the thyroid.⁴⁶ Interestingly, it has been shown that exogenous TRAIL can suppress the development of autoimmune thyroiditis via altering the function of immune response cells.⁵⁷ This finding may lead to the design of a novel therapeutic strategy for treatment of autoimmune thyroiditis.

PATIENT EVALUATION AND DIFFERENTIAL DIAGNOSIS

HT primarily presents with symptoms of altered thyroid function. Early in the course of the disease, the patient is usually euthyroid but can experience clinical thyrotoxicosis because of the breakdown of thyroid

Fig. 69.4 Apoptosis occurs in thyrocytes from Hashimoto's thyroiditis. The apoptotic cells were detected with ApopTag staining Kit, where the nuclear fragmented DNA is detected by the brown color.

KEY CONCEPTS

IMMUNOLOGIC FEATURES IN HASHIMOTO'S THYROIDITIS

- >> Expression of major histocompatibility complex (MHC) class II antigens, especially human leukocyte antigen (HLA)-DR antigen on thyrocytes
- >> Possible defects in CD4⁺CD25⁺ regulatory T cells
- >> Changes in the thyroid microenvironment
- >> Cytokine-induced apoptosis in thyrocytes
- >> Recognition of thyroid antigens by T cells
- >> Production of antithyroid peroxidase (TPO) antibody and antithyroglobulin antibody
- >> Production of immune complexes

follicles with the release of thyroid hormones. In contrast, late in the disease, the patient is often hypothyroid due to progressive destruction of the thyroid gland. The most common outcome of HT is hypothyroidism. HT is not usually life-threatening, but its natural history is quite long in evolution and may confound clinicians.

A consistent physical sign seen in HT is an enlarged thyroid gland. The goiter is often symmetrically large and feels very firm, with fine nodularity present. The size of an enlarged thyroid gland and the number of nodules are variable, depending on the amount of lymphocytic infiltration, the formation of fibrosis, and the degree of compensatory hyperplasia. Lymph nodes surrounding the gland often become enlarged, and lymphoma must be excluded. Sometimes patients show symptoms of other autoimmune diseases, such as generalized vasculitis with urticaria and nephritis, and these are believed to be caused by the cross-reaction of antithyroid autoantibodies with other tissues or the presence of circulating immune complexes containing thyroid antigens, predominantly thyroglobulin.

General laboratory findings are not very useful in making a diagnosis of HT other than conducting tests of the thyroid status. However, screening tests for specific autoantibodies against thyroid (antithyroglobulin and antithyroid TPO) may be helpful. In the early phase of the disease, thyroid hormone levels may be normal, high, or low. An increased TSH in the presence of normal thyroid hormones (T_4 and T_3) may presage clinical hypothyroidism. HT patients with hyperthyroidism are differentiated from those with GD by the demonstration of patchy or decreased uptake on a radioiodine scan of the thyroid.

Sometimes it may be difficult to differentiate HT from GD and other types of thyroiditis (focal lymphocytic thyroiditis, subacute thyroiditis, Riedel's thyroiditis). On occasion, the rapid enlargement of one lobe of the thyroid gland in HT also needs to be differentiated from malignant lymphoma or thyroid carcinoma. The fibrous variant of HT may also mimic carcinoma. In subacute thyroiditis, the involvement of the gland is focal, whereas in HT the gland is diffusely nodular and only rare nodules may be spared from the process. Often, fine-needle biopsy will be necessary to provide pathologic diagnosis. Cytologically, HT is

characterized by the presence of lymphoid infiltration of follicles, follicular cells with oxyphilic changes of varying degrees, polymorphous lymphocyte populations, and histiocytes.

■ POSTPARTUM THYROIDITIS ■

Postpartum thyroiditis is characterized by the development of transient thyrotoxicosis and/or hypothyroidism during the first 6 months of the postpartum period. A significant percentage of patients (25–30%) will suffer from chronic hypothyroidism. The symptoms of postpartum thyroiditis were first described by H.E.W. Robert in 1948, but the nature of the disease was not fully established until 1976. The incidence of postpartum thyroiditis has been reported to range from 2% to 21% in different races and geographical locations. However, a much narrower range of 5–8% is generally accepted.

GENETIC AND ENVIRONMENTAL FACTORS

The development of postpartum thyroiditis, like other AITDs, is thought to involve genetic and environmental factors. A familial form of postpartum thyroiditis has been reported.⁵⁸ HLA haplotypes (DR3, DR4, DR5, DR7) are positively or negatively associated with disease risk, emphasizing the role of genetic predisposition.

Iodine consumption may affect the incidence or severity of postpartum thyroiditis and this concept is in agreement with the fact that the administration of iodine exacerbates AITD.^{28, 29, 59} One study performed by Kampe *et al.* showed that the administration of 150 µg of iodine daily increased the severity of hypothyroidism in women with postpartum thyroiditis.⁵⁹ A history of smoking may also be a risk factor in the development of postpartum thyroiditis.⁶⁰

PATHOGENESIS

Complement-fixing TPO antibodies are present in a majority of patients with postpartum thyroiditis, and the titer of this autoantibody is closely associated with the severity of the disease.⁶¹ Although the TPO antibody

response is significant and dramatic, the role it plays in the pathogenesis of postpartum thyroiditis remains unknown. As the histomorphologic changes seen in postpartum thyroiditis are the same as in HT, it is possible that the antibody only reflects the degree of damage to the thyroid gland and that the damage is executed by lymphocyte-, complement-, and apoptosis-mediated mechanisms similar to HT. However, it should be noted that the pathways leading to the final presentation of the disease appear somewhat different between these two types of thyroiditis.

It has been well known that pregnancy can induce dramatic suppression of both humoral and cell-mediated immunity, for example, a decrease in helper T-cell number and an increase in suppressor T-cell number.⁶² In the postpartum state, reversal of this phenomenon may induce rebound activation of autoimmune diseases. Obviously, rebound of suppressive immunity itself is not the sole factor in inducing postpartum thyroiditis. A number of studies have indicated that HLA antigens, particularly DR antigens, are associated with the disease. There is a positive correlation of the syndrome with DR5. Negative correlation between the disorder and DR2 has been observed,⁶³ suggesting that DR2 might confer a protective effect. Frequencies of DR3, DR4, and DR7 have been found to be increased in postpartum thyroiditis.⁶⁴

Lymphocyte subsets and functions are significantly altered in postpartum thyroiditis. The ratio of B cells to T cells within thyroid glands is increased, as is the ratio of helper T cells to suppressor T cells.⁶⁵ Functionally, T-cell activation is significantly increased.⁶² All these changes may present a picture very similar to the one seen in HT. Involvement of an apoptotic process in postpartum thyroiditis is possible. 2-Methoxyestradiol, an endogenous estrogen metabolite, is able to induce thyroid cell apoptosis,⁶⁶ suggesting that there may be a link between thyroid cell apoptosis and female hormones or their metabolites.

PATIENT MANAGEMENT

Treatment is not usually recommended for the thyrotoxic phase unless symptoms are severe. As thyrotoxicosis in postpartum thyroiditis is caused by hormone release from the damaged gland and is not secondary to increased synthesis and secretion of thyroid hormones, antithyroid medicines are not useful.

In the hypothyroid phase of postpartum thyroiditis, the management of this disorder is somewhat similar to that of hypothyroidism caused by other diseases. Therefore, thyroid hormone therapy is not required unless the hypothyroidism is clinically and biochemically significant. Administration of T₄ prevents hypothyroid symptoms, but it does not alter the course of the disease.

PATIENT EVALUATION AND DIFFERENTIAL DIAGNOSIS

The classic clinical course of postpartum thyroiditis consists of a sequence of two phases, hyperthyroidism and hypothyroidism. The hyperthyroid phase is followed by the hypothyroid phase and the recovery. The hyperthyroidism is often too mild to be recognized or even does not occur at all. During this phase, irritability and lack of energy are prominent, even in autoantibody-positive women who do not develop thyroid dysfunction. In contrast, the symptoms of the hypothyroid phase may be profound. Because psychomotor retardation is a prominent feature of both diseases, thyroid function studies are recommended in the evaluation of women with clinically significant symptoms of postpartum depression.

About 80% of the patients are euthyroid within 12 months after delivery. However, many of them will have a recurrence of postpartum thyroiditis with subsequent pregnancies, and they are also at a greater risk of becoming permanently hypothyroid. In addition, patients are more likely to become persistently hypothyroid when they have relatively high autoantibody titers or lack a hyperthyroid phase of the disease.

Results from laboratory tests need to be analyzed with consideration given to the two phases in the course of the disease. The levels of TSH are usually a little lower or at the lower limit of detection in the hyperthyroid phase, whereas its levels are increased during the hypothyroid phase. Thyroid hormones are also consistent with the two-phase changes. Antithyroid autoantibodies, especially the anti-TPO antibodies, are present in most patients. TRAb is usually not found unless there is coexisting GD.

The first phase (hyperthyroidism) of postpartum thyroiditis is sometimes difficult to distinguish from GD, although the latter commonly ameliorates during pregnancy. If necessary, the thyroid radioactive iodine uptake (RAIU) test can be performed to differentiate between these two diseases. In postpartum patients, I-123 should be used rather than I-131, and appropriate precautions should be taken to avoid exposure to the child. A low RAIU uptake is consistent with postpartum thyroiditis, while a high one is consistent with GD.

The relation between women with postpartum thyroiditis and the outcome of their babies has received much attention. Infants born to women who suffer from the disease show a decrease in their growth during the first 30 days, though Apgar scores, birth weight and length, and levels of thyroid hormones are not significantly different from those of infants born to unaffected women.⁶⁷ Low IQ is also associated with postpartum thyroiditis of the mother.⁶⁸

Diabetes and related autoimmune diseases

George S. Eisenbarth

70

Diabetes mellitus is a heterogeneous group of disorders characterized by glucose intolerance and hyperglycemia. The clinical manifestations of this disease are the result of either an absolute or a relative deficiency of insulin secretion. An expert committee of the American Diabetes Association proposed four categories of diabetes, based on etiology rather than the age of disease onset (e.g. juvenile-onset versus adult-onset) or the requirement for insulin therapy (insulin-dependent versus noninsulin-dependent).¹ The categories are type 1 (formerly termed insulin-dependent diabetes – IDDM); type 2 (with a major component of insulin resistance); diabetes with known genetic mutations (e.g. the maturity-onset diabetes of youth syndromes with mutations in glucokinase, hepatic nuclear factor genes etc.); and gestational diabetes (Table 70.1). Type 1 diabetes is divided into types 1A (immune mediated) and 1B (idiopathic loss of insulin secretion), depending primarily on the presence or absence respectively of anti-islet autoantibodies.

The subject of this chapter is type 1A or immune-mediated diabetes, and there is now convincing evidence that this form results from immune-mediated destruction of the cells that produce insulin. Despite older designations for this category, approximately the same number of adults develop type 1A diabetes as do children, and many individuals early in the course of type 1A diabetes are not ‘insulin dependent’ but can transiently be treated with oral hypoglycemic agents. The incidence of type 2 diabetes increases dramatically with age, whereas that of type 1A changes relatively little with age (less than threefold).² Thus, when a child develops diabetes they usually (>90% for non-Hispanic white children) have type 1A diabetes mellitus. There is, however, heterogeneity of diabetes even among children with the disorder. For example, almost half of African-American and Hispanic-American children who develop diabetes do not have type 1A, but rather primarily type 2.³ Given such heterogeneity, it is likely that the diagnostic classification of diabetes will in the future depend upon the immunologic parameters to be discussed and the identification of specific genetic mutations associated with specific disorders of glucose metabolism.

The information indicating that type 1A diabetes is an immune-mediated autoimmune illness has greatly increased during the past two decades. The recognition that there might be a form of ‘juvenile’ or

insulin-dependent diabetes of autoimmune origin came from the observation that diabetes was often associated with disorders thought to be of autoimmune origin, such as Addison’s disease, Graves’ disease and thyroiditis. Nevertheless, considerable confusion existed because of the failure to separate diabetes into distinct disease categories (type 1 versus type 2). Although insulinitis had been observed in a few children who had come to autopsy shortly after the development of diabetes, this was an extremely rare event for diabetes as a whole.⁴

Studies of monozygotic twins with diabetes revealed very different patterns of inheritance for insulin-dependent and noninsulin-dependent diabetes mellitus, and two major forms of the disease were proposed. Specific HLA alleles were found to be associated with the insulin-dependent form,⁵ and in 1974 cytoplasmic islet cell autoantibodies were found for diabetic patients with polyendocrine autoimmunity (e.g. Addison’s disease).⁶ Islet cell autoantibodies were then found to be

KEY CONCEPTS

TYPE 1A DIABETES IS AN AUTOIMMUNE DISEASE

- >> Genetic and familial clustering of diabetes and additional autoimmune disorders
- >> Presence of high-affinity autoantibodies and T cells reactive to islet cell autoantigens
- >> Strong HLA association (DR3/DR4)
- >> Ability to transfer the disease in animal models through adoptive transfer of islet cell-reactive T-cell clones
- >> Recurrence of disease in pancreas transplanted between identical twins
- >> Regulatory T cells important; their loss in IPEX syndrome leads to neonatal diabetes

Table 70.1 Classification of diabetes mellitus (DM)

Diabetes mellitus	Previous designations	Etiologic distinctions	Clinical distinctions
Type 1 A. Immune-mediated B. Idiopathic	Juvenile onset/IDDM Type 1.5/Flatbush DM	β -cell destruction Immune Unknown	Both result in insulin dependence, with loss of β -cells
Type 2	NIDDM	Insulin resistance and relative insulin deficiency	Oral hypoglycemic agents are effective early in the disease
Other specific types	MODY Secondary diabetes	Specific genetic defects Pancreatic disease Endocrinopathies Chemical induced Infection related Immune-mediated forms Genetic syndromes	Specific mutations identified and defined clinical syndromes
Gestational	Unchanged		Onset during pregnancy

IDDM, insulin-dependent diabetes; MODY, maturity-onset diabetes of youth; NIDDM, non-insulin dependent diabetes.

present prior to the development of diabetes, and studies of monozygotic twins of patients with type 1 diabetes led to the observation that this was a chronically progressive autoimmune disorder.⁷ In identical twins developing diabetes, islet cell autoantibodies and loss of insulin secretion preceded the development of diabetes by years. As discussed below, the measurement of anti-islet autoantibodies has improved dramatically during the past two decades, and for many individuals the development of type 1A diabetes can now be predicted.

Despite the emphasis on anti-islet autoantibodies, most investigators believe that T cells, and not autoantibodies, mediate the immune destruction of insulin-producing cells.⁸ Studies of T cells have benefited from the discovery of two animal models of type 1A diabetes, the NOD mouse and the BB rat.⁸ In animal models diabetes can be transferred to nondiabetic animals by T-cell clones. In addition, a clinical observation by Sutherland and co-workers⁹ was particularly informative in terms of demonstrating the importance of T cells in this disease. They transplanted the tail of the pancreas from monozygotic twins who had not developed diabetes into their respective twin pairs with more than a decade of diabetes. The transplanted islets were invaded by lymphocytes, and islet β cells (the cells that produce insulin) were specifically and rapidly destroyed.

Despite considerable progress in studies of type 1A diabetes, a series of basic and clinical questions remain unanswered or have only partial answers (Table 70.2). This chapter reviews current knowledge concerning many of these questions.

DIAGNOSIS

The demonstration of elevated plasma glucose is the sine qua non for diagnosis of diabetes mellitus. Recent recommendations by the American Diabetes Association have lowered the diagnostic level of fasting glucose from 140 mg/dl (7.8 mmol/L) to 126 mg/dL (7.0 mmol/L). Other

Table 70.2 Key questions in type 1A diabetes

Basic science questions

What genes determine type 1A diabetes susceptibility?
What triggers or suppresses the activation of autoimmunity?
What are the major target molecules and is there a primary autoantigen?
What are the effector mechanisms for islet destruction?

Clinical questions

Is type 1A diabetes predictable?
Is the rate of progression to overt diabetes predictable?
Is type 1A diabetes preventable?

diagnostic criteria include a random plasma glucose level >200 mg/dL (11.1 mmol/dL) or a plasma glucose level >200 mg/dL (11.1 mmol/dL) 2 hours after ingestion of 75 g oral glucose (the oral glucose tolerance test – OGTT).

The clinical signs and symptoms associated with hyperglycemia and osmotic diuresis (e.g. polyuria and polydipsia) are recognized by clinicians and lay people alike, making the diagnosis relatively straightforward. Insulin deficiency, if untreated, leads to the utilization of fats for fuel, with subsequent metabolism of fatty acids and the production of ketoacids. Thus, the presentation of ketonuria, ketonemia and ketoacidosis, often associated with nausea or hyperventilation, is an important clinical feature. Unexplained weight loss, along with the classic signs and symptoms mentioned above, is highly suggestive of the diagnosis of diabetes. Despite the classic signs and symptoms, approximately 1 in 200 children die at the onset of type 1 diabetes. If the first healthcare provider to see the child fails to make a diagnosis of diabetes, the child may subsequently present with severe ketoacidosis and may develop cerebral edema, which is usually fatal.

Although not specifically recommended as a diagnostic criterion, an elevated glycosylated hemoglobin concentration (HbA1c) may also be useful for diagnosis. The HbA1c level correlates with mean glucose levels over several months and eventually with the development of diabetic complications, including diabetic retinopathy.

The diagnosis of specific diabetic syndromes, including type 1A diabetes, requires further information. Several clinical criteria increase or reduce the probability that an individual has type 1A diabetes (e.g. increase: onset at age <35, nonobese, presence of ketoacidosis, immediate therapy with insulin required, family or personal history of organ-specific autoimmunity; decrease: age of onset >35, effective therapy with oral hypoglycemic agents, African-American or Hispanic-American child, obesity). These clinical criteria are, however, imprecise guidelines at best. For example, as many as 10% of obese white adults presenting with diabetes have type 1A. The hallmark of type 1 versus type 2 diabetes is the early (several years after diagnosis) development of severe insulin deficiency. The connecting peptide (C-peptide) of the proinsulin molecule is secreted in equimolar quantity to insulin by pancreatic β cells. Within 3 years of the onset of type 1A diabetes, most children have a severe impairment of insulin secretion with low C-peptide. The range of C-peptide secretion, however, is large at the onset in both type 1 and type 2 diabetes. Secretion is influenced by metabolic control, such that determination of C-peptide at onset has limited diagnostic utility in distinguishing type 1 from type 2 diabetes. The maintenance of C-peptide secretion can also be used as a measure of effective immunotherapy in clinical trials.

It should be recognized that both type 1A and type 2 diabetes are relatively common disorders, and thus individuals might have both diseases. Type 2 diabetes would be manifested by resistance to insulin, such that overt hyperglycemia will present earlier in the course of the islet β -cell destruction associated with type 1A diabetes. It has been proposed ('accelerator hypothesis') that type 1A and type 2 diabetes both result from metabolic changes associated with insulin resistance, and that type 1A represents a more severe form of diabetes with anti-islet autoimmunity. Data leading to this hypothesis are slightly faster growth and higher body mass index (BMI) in children who develop type 1A diabetes.¹⁰

CLINICAL PEARLS

- >> Type 1A diabetes can occur at any age. Testing of islet cell autoantibodies identifies 10% of adults (thought to have type 2 diabetes) as having type 1A diabetes.
- >> Half of African-American and Hispanic-American children are negative for anti-islet autoantibodies and have type 2 or type 1B diabetes.
- >> Organ-specific autoimmunity (in particular celiac disease, thyroid disease, Addison's disease and pernicious anemia) is greatly increased in patients with type 1A diabetes.
- >> The more common the organ-specific autoimmune disease in the general population the more common the disease in patients with type 1A diabetes. For example, thyroid autoimmunity is common and routine TSH testing is advised.
- >> In diabetic patients with decreasing insulin need or severe hypoglycemia, rule out Addison's disease.

Given the improved genetic prediction of type 1A diabetes with genes influencing immune function, it is unlikely that insulin resistance is a major factor in the initiation of islet autoimmunity,¹¹ although insulin resistance is likely to reveal overt hyperglycemia earlier in the course of immune-mediated β -cell destruction.

The best immunologic markers for distinguishing type 1A from other forms of diabetes is the presence of islet cell autoantibodies. Diagnostic accuracy depends on the sensitivity and specificity of the autoantibody assays employed. Assays for autoantibodies reacting with insulin, glutamic acid decarboxylase (GAD65) and ICA512 (IA-2), when performed with fluid-phase assays (not ELISA), can be set such that fewer than 1 in 100 nondiabetic individuals are positive. One or another of these three autoantibodies is present in approximately 95% of children with recent-onset type 1A diabetes. However, approximately half of Hispanic-American children presenting with diabetes do not express any of the three anti-islet antibodies (compared to approximately 10% of non-Hispanic white children). We believe that the majority of the antibody-negative population represent a type 2 diabetes variant, although there are important genetic variants, including half of neonatal diabetes determined by mutations of the sulfonylurea receptor Kir6.2 gene¹² and multiple MODY genes.¹³

■ EPIDEMIOLOGY/INCIDENCE ■

Type 1A diabetes is one of the most common chronic diseases of childhood and is the most common type of diabetes in persons under 40. Diabetes is the leading cause of blindness, amputations and end-stage renal disease, and is a major factor contributing to cardiovascular disease and premature death. It typically presents in children (with a peak onset at 12–13 years of age), but it may occur at any age and in all racial groups, with approximately similar prevalence in both females and males.

KEY CONCEPTS

EPIDEMIOLOGY AND INCIDENCE OF TYPE 1A DIABETES

- >> One of the most common chronic diseases of childhood and the most common type of diabetes in persons under 40 years of age.
- >> The leading cause of blindness, amputations, and end-stage renal disease, and contributes to premature death.
- >> Peak age of onset is 12–13 years, but may occur at any age, in all racial groups, with equal prevalence between males and females.
- >> More children are diagnosed in the fall and winter months, but it is likely that this reflects factors that bring children to medical attention.
- >> The incidence of type 1A diabetes has been increasing in many countries.
- >> No conclusive evidence exists for an association between vaccination and incidence of type 1A diabetes.

The annual incidence of type 1A diabetes varies dramatically. In children the incidence is approximately 15/100 000 in the United States, 35/100 000 in Finland, and fewer than 1/100 000 in Japan. The prevalence in the USA is approximately 1/300, and 90% of children developing diabetes do not have a first-degree relative with the disorder. Approximately 1/20 first-degree relatives of patients develop the disease. The risk to offspring of a father with type 1A diabetes is approximately twice that of offspring of an affected mother. In the US, non-Hispanic white Americans are approximately 1.5 times more likely to develop type 1A diabetes than are other groups.

The prevalence of type 1A diabetes is greatest in countries where the predominant population is Caucasian. For example, it is most prevalent in Finland and Sardinia and rare in Japan, Korea and China. A child in Finland has a 35 times greater risk of developing diabetes than a child in Japan. In Japan, for example, monozygotic twins of patients with type 1A diabetes and their first-degree relatives have a risk of diabetes similar to that of twins and relatives in the USA.¹⁴ This suggests that the bulk of differences between countries relates to genetic differences and not environmental factors. Studies of migrant populations from developed countries have failed to reveal major differences in the incidence of diabetes based on migration from a high-incidence to a lower-incidence country.¹⁵ Nevertheless, there are less well characterized populations where the incidence may have changed dramatically with migration, e.g., Yemenite Jews migrating to Israel.¹⁶

Seasonal variations in the incidence of type 1A diabetes have been well documented, with more children presenting with the disease in the fall and winter months. This seasonal variation has been ascribed to potential viral infections that destroy β cells; however, with increased knowledge of the natural history of type 1A diabetes it is more likely that such seasonal variation may simply reflect factors (such as viral infections) that either bring children to medical attention or produce insulin resistance when limited islet β -cell mass remains.

NATURAL HISTORY

Studies over the past decade in humans are defining details of the chronology of development of type 1A diabetes. In addition, studies in animal models have contributed to a greater understanding of the pathogenesis of the disease. At present, there are three major hypotheses (described below) concerning the natural history of type 1A diabetes, with a fourth having almost no supporters. The fourth hypothesis, which was prominent two decades ago, was that type 1A diabetes was an acute disorder induced by viral infection. If the development of diabetes is acute it is likely to be extremely rare, given studies of both relatives and the general population. Anti-islet autoantibodies almost always precede diabetes by years, as does the loss of first-phase insulin secretion.^{17,18}

- **Hypothesis 1** Type 1A diabetes is a chronic and progressive disorder resulting from immune-mediated destruction of islet β cells.^{7,19} A corollary of this hypothesis is that as immunologic and immunogenetic assays are refined, one should be able to predict both the risk of diabetes and the approximate time of progression to diabetes, with different individuals progressing at different rates. This hypothesis is encapsulated in the division of type 1A diabetes into a series of stages (I, genetic susceptibility; II, triggering of autoimmunity; III, active immunity; IV, loss of insulin secretion; and V, overt diabetes) (Fig. 70.1).^{7,19}

- **Hypothesis 2** Type 1A diabetes is preceded by a long prodromal phase of autoimmunity, but actual islet β -cell destruction is acute and occurs at the end of the process.
- **Hypothesis 3** Type 1A diabetes results from 'multiple' hits, perhaps viral, and thus develops slowly, but would be difficult to predict as the 'hits' are not predictable.²⁰

It is possible that a combination of all three hypotheses will eventually be found to apply to different individuals developing diabetes. For example, an identical twin with diabetes who receives half of the pancreas from their nondiabetic twin rapidly develops recurrent diabetes within several weeks.⁹ Thus, the immune system has the potential to rapidly destroy human β cells. Nevertheless, there is considerable evidence that the first hypothesis is generally applicable. It reflects the progressive loss of first-phase insulin secretion that precedes diabetes, and the chronic loss of C-peptide secretion (over years) after the diagnosis of diabetes. This hypothesis is also consistent with recent analysis of β -cell loss and regeneration in NOD mice prior to diabetes.²¹

Despite evidence for progressive loss of β cells in the NOD mouse,²¹ there is evidence for important changes in the immune system at the onset of diabetes. In the NOD mouse, splenocytes from recently diabetic – but not nondiabetic – mice transfer diabetes. Close to the time of diabetes, but not at early ages, NOD mice destroy islet transplants.²² Finally, anti-CD3 therapy produces long-term improvement in blood sugar levels if given at the onset of disease, but not with early treatment.²³

STAGE I: GENETIC SUSCEPTIBILITY

TWIN STUDIES

Monozygotic twins of patients with type 1A diabetes have approximately a 50% concordance rate for type 1A diabetes. This concordance is markedly different from that of dizygotic twins (5%), who have a risk similar to a sibling of a patient with type 1A diabetes. This

difference reflects a significant role for genetic factors, but suggests that environmental and possibly somatic mutations or other stochastic events may also play a significant role in the pathogenesis. Although the risk of a discordant twin progressing to type 1A diabetes decreases proportionately with the duration of discordance, twins can become concordant after many years. In a prospective study involving 187 monozygotic twins from the UK and the USA who were discordant at the time of enrolment, 47 became concordant, with a range of time of onset of 0.4–39 years. The median discordance time of the twin pairs was 4.2 years, and 25% became concordant after 14 years of discordance.²⁴

HLA GENES

A major determinant of genetic susceptibility resides in the MHC class II region (*IDDM1*). HLA class II molecules, particularly DR and DQ, account for approximately 50% of the genetic risk for type 1A diabetes.²⁵ As the MHC region displays a significant degree of linkage disequilibrium (e.g. specific DQ and DR alleles are nonrandomly associated with each other) associations of HLA with disease must be thought of as haplotype specific and not allele specific. Class I HLA alleles can also influence disease, and it is possible that unknown genes linked to the HLA region are important. Nevertheless, the identification of HLA class II alleles associated with high, moderate, low risk and even 'protection' is useful in disease prediction (Table 70.3).

Individuals with the highest risk for type 1A diabetes in the USA express both DQA1*0501-DQB1*0201 (DQ2), which is almost always

inherited with DRB1*0301, and DQA1*0301-DQB1*0302 (DQ8), inherited with DRB1*0401 or *0402. These individuals have been referred to as DR3/DR4 or DQ2/DQ8 heterozygotes. The genotype, DQ2/DQ8 (DR3/DR4), is commonly observed in type 1A diabetics. Although only 2% of children in the USA have this genotype, they constitute approximately 40% of those developing diabetes.²⁶ Observations of transmission frequencies of particular haplotypes have helped illustrate the importance of certain haplotypes in contributing to diabetes susceptibility. For example, analysis of the Human Biological Data Interchange (HBDI) family collection has revealed that DQA1*0501-DQB*0201 and DQA1*0301-DQB1*0302 are transmitted to more than 80% of diabetic children. DQB1 alleles without an aspartic acid at position 57 of the β chain have been proposed to determine diabetes risk. However, no simple amino acid rule adequately describes the risk associated with DQ alleles.

HLA DQ alleles have also been associated with dominant protection from type 1A diabetes.²⁷ Approximately 20% of the general population have DQA1*0102-DQB1*0602, the HLA haplotype that provides dominant protection from type 1A diabetes. Interestingly, autoantibody-positive relatives of affected individuals who express the HLA haplotype DQA1 0102, DQB1*0602 are protected from progression to diabetes, albeit not completely.²⁸

HLA class I and DP alleles are also associated with diabetes risk. For example, the A24 allele is associated with early age of onset of type 1A diabetes.²⁹ There are probably additional loci linked to HLA, such as loci near microsatellite D6S2223, also conferring risk.

NON-HLA GENES

Genome-wide screens for loci linked with diabetes (using microsatellite markers from all of the chromosomes) have led to the identification of 18 genetic loci contributing to diabetes susceptibility in the NOD mouse, and over 15 in humans, with variable statistical significance (Table 70.4). However, for the great majority of these putative loci no actual genes have been identified.

Because the autoimmune response against the β cell-specific molecule insulin is a major component of type 1A diabetes, the insulin gene would be an ideal candidate locus. In fact, polymorphisms in the 5' flanking sequence (promoter region) of the insulin gene have been associated with diabetes risk, and account for about 10% of the familial aggregation of type 1A diabetes.³⁰ The insulin gene is located on the short arm of chromosome 11 and has been termed *IDDM2*. Polymorphisms in the 5' sequence leading to alterations in insulin gene expression could be envisaged as potentially modulating the development of tolerance in the thymus or yolk sac. A low level of insulin gene expression in the thymus may allow insulin-reactive T cells to escape negative selection. The insulin gene polymorphism (larger repeat region), which results in greater thymic expression of proinsulin, is associated with protection.^{31,32} The mutated gene underlying the autoimmune polyendocrine syndrome type I (APS-I), namely AIRE (autoimmune regulator gene) appears also to control insulin expression in the thymus and hence diabetes risk.³³

Some of the loci identified through genome-wide screens for linkage have not been replicated by different groups, although a few, such as PTPN22, have been confirmed in multiple studies.³⁴ The reasons for this lack of reproducibility may include the following: genetic heterogeneity in different populations; heterogeneity of disease phenotypes; ethnic differences; statistical 'artifacts'; and differences in the markers used. It is possible

that genetic heterogeneity between different families having different non-MHC genes may underlie the inability of sibling-pair studies to identify loci accounting for a major proportion of the familial aggregation of type 1A diabetes. Three potential patterns of inheritance for diabetes will be addressed: monogenic, polygenic and oligogenic (Table 70.5).

In 1989, Pnini Vardi identified a unique family with a high frequency of type 1A diabetes⁸⁶. This Bedouin Arab family consisted of over 250 members, of whom 18 were affected (Fig. 70.2). A genome-wide scan for linkage in this family revealed that the risk for diabetes was associated with a

susceptibility locus on chromosome 10 which is termed *IDDM17*. In family members expressing the DR3 or DR4 haplotypes, the risk for diabetes was 30%, as opposed to <2% for those members who did not have a DR3 or DR4 haplotype. Linkage analysis and association studies revealed that in this family a pattern of oligogenic inheritance may underlie disease susceptibility.

RODENT MODELS

Studies in animal models have contributed greatly to our understanding of the pathogenesis of type 1A diabetes. Numerous models exist, both induced (e.g. with alloxan, streptozotocin treatment) and spontaneous (e.g. NOD mouse, BB rat) (Table 70.6). Some important advantages of an autoimmune model include access to the pancreas at various stages in the immunopathology; ability to breed and genetically manipulate the animals; and intervention strategies that can be employed at various disease stages (e.g. preinsulinitis, insulinitis/presymptomatic stage etc.).

NOD MOUSE

The best-studied animal model for type 1A diabetes is the nonobese diabetic (NOD) mouse, which develops diabetes spontaneously. In the NOD mouse, cellular and humoral immune responses specific for β cells are present, anti-insulin autoantibodies precede overt diabetes, and disease is associated with specific MHC alleles. Pancreatic insulinitis in the NOD mouse can be detected as early as 2 weeks with electron microscopy, and becomes detectable by light microscopy at 4–5 weeks of age. Approximately 80% of female mice and 20% of male mice progress to diabetes by 30 weeks of age. The reason for the excess of female cases is unknown, but may be related to the effects of sex hormones.

Multiple genetic loci in this mouse determine disease susceptibility, with the MHC (termed *Idd1*) being necessary but not sufficient for disease. The class II region in NOD mice encodes the I-A^{g7} molecule, the ortholog of the human class II DQ8 and DQ2. I-A^{g7} is unique among the known I-A molecules in that it has a serine instead of an aspartic acid at position 57 of the β chain. Like a number of normal strains, NOD mice do not express I-E (the murine ortholog of HLA-DR) because of a mutation in the E α promoter. The introduction of a normal I-E α gene inhibits

Table 70.5 Three genetic models of type 1A diabetes inheritance

Monogenic model

Susceptibility to type 1A diabetes and other endocrine and nonendocrine autoimmune diseases can be determined by a mutation in a single gene. An example is the autoimmune polyendocrine syndrome type I (APS-I) with a mutation in the autoimmune regulator (AIRE) gene.⁴⁸

Polygenic model

A major role for class II molecules (DQ, DR) in determining susceptibility for type 1A diabetes is well recognized. In the NOD mouse model more than 15 non-MHC loci have been found to contribute to diabetes risk. The idea that multiple genetic polymorphisms, each contributing a small component to disease susceptibility, is a popular model.

Oligogenic model

Diabetes risk may be determined by HLA alleles in conjunction with one or two non-MHC disease genes in each family. For different families the specific major 'diabetogenes' would differ. This model is supported by studies of a large Bedouin Arab family⁴⁹ and the finding of a risk of 40% for DQ2/DQ8 siblings of patients with type 1A diabetes.³⁹

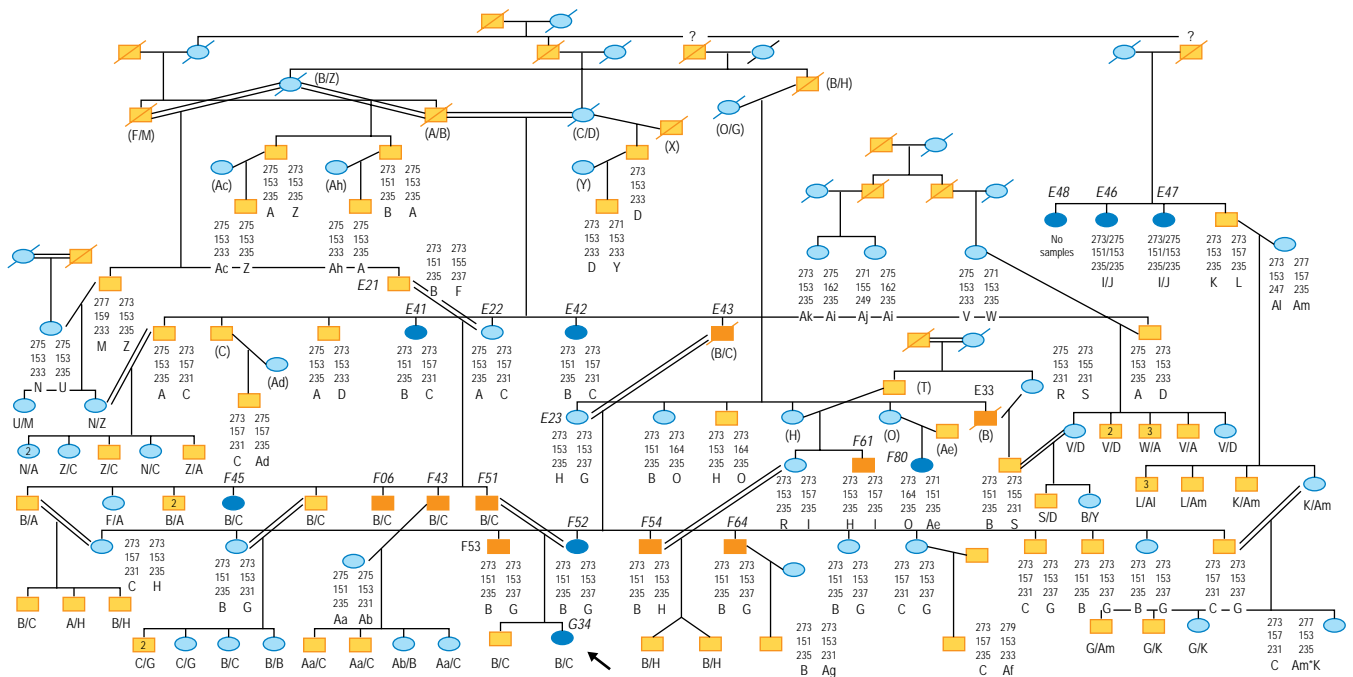

Fig. 70.2 Type 1A diabetes inheritance. Family tree in which 18 members have developed type 1 diabetes and diabetes appears to be inherited as an autosomal recessive mutation at a locus on chromosome 10 plus typical type 1 HLA alleles. The B haplotype on chromosome 10 occurs in the majority of patients with diabetes (numbers refer to chromosome 10q25.1 microsatellite alleles) and diabetics have homologous B like 10q25.1 regions for other diabetic haplotypes (e.g. haplotypes, Ae, O, I, J, C, G, and H).

the development of diabetes in the NOD mouse, implying that its absence is important.³⁵ Transgenic NOD mice expressing a 'normal' I-A, or with amino acid substitutions at positions 56 and 57 of the NOD I-A^{g7}, are protected from disease. Recent studies suggest that insulin may be a primary autoantigen for the disorder, and mutation of a single amino acid of insulin prevents the development of diabetes.³⁶

BB RAT

The BB rat also develops diabetes spontaneously, with equal frequency among males and females.⁸ Ninety percent of both sexes developing insulinitis progress to overt diabetes between 50 and 90 days of age. Selective breeding of BB rats resulted in the production of a diabetes-prone (DP) and a diabetes-resistant (DR) strain.

Genetic susceptibility for type 1A diabetes in the BB rat is also determined in part by the MHC genes. In the BB rat, diabetes is independent of class I alleles but requires the MHC class II haplotype RT-1U (*Iddm2*), in which at least one allele must be present for diabetes to develop. A second locus (*Iddm1*) is inherited in an autosomal recessive manner and is responsible for T-cell lymphopenia in these animals, determined by a frameshift mutation of an Ian (immune associated nucleotide) gene.³⁷ The DP-BB rat is deficient in T cells expressing the surface antigen RT6. RT6 is a surface marker that appears to distinguish a subset of T cells capable of immunoregulation, as adoptive transfer of these cells into a DP-BB rat abrogates diabetes. In addition, monoclonal antibodies targeting RT6 can induce β -cell destruction in nonlymphopenic, diabetes-resistant (DR) BB rats.

The DR-BB rats are nonlymphopenic and diabetes can be induced either by the administration of RT6 monoclonal antibodies or by infection with the Kilham rat virus. The Kilham rat virus does not infect β cells but is believed to alter immune regulation.³⁸ Table 70.6 lists several animal models of type 1A diabetes.

■ TRANSGENIC MODELS ■

The use of transgenic and knockout technology has allowed investigators to begin to determine the role of various immune factors in the etiology and pathology of type 1A diabetes. In these models, the breakdown of organ-specific tolerance can be examined by creating DNA constructs that allow tissue-specific expression of the transgene under the control of tissue-specific promoters (e.g. insulin promoter). Most of the transgenic models of type 1A diabetes involve the NOD mouse, and a brief summary of some of these studies is provided (Table 70.7).

NOD mice that have been crossed with mice having a target mutation of the μ chain in the IgM heavy chain do not develop diabetes,³⁹ suggesting that B lymphocytes play an important role in the disease process. As autoantibodies do not appear to be directly pathogenic to β cells, the role of B cells in the pathogenesis of type 1A diabetes appears to be that of antigen presentation. When B cell-deficient ($MT^{-/-}$) mice were crossed with NOD mice expressing a B7.1 transgene in the pancreatic β cells, progression to diabetes was accelerated, suggesting that B-cell presentation can be bypassed.

The perhaps overly simplistic hypothesis that Th1 cells are destructive and Th2 protective is the basis for efforts to skew the cytokine environment towards Th2 cytokines. In support of this idea, the administration of IL-4 or IL-10 has been associated with disease protection in NOD mice, whereas systemic administration of Th1-type cytokines, IL-12 and TNF- α ⁴⁰ can precipitate disease. However, studies of transgenic and knockout NOD models involving cytokines have suggested that the Th1/Th2 paradigm is an oversimplification. For example, NOD mice expressing an IL-4 transgene specifically in the islet β cells show protection from diabetes, whereas IL-4 knockout NOD mice do not show accelerated diabetes. In addition, anti-IFN- γ treatment prevents diabetes developing in the NOD mouse, but IFN- γ -deficient NOD mice continue to develop diabetes, albeit at a reduced rate.⁴¹ Furthermore, whereas NOD mice administered IL-10 are protected from diabetes,³³ mice expressing an IL-10 transgene specifically in the islet β cells develop accelerated diabetes.⁴² Although the reasons for these differences remain to be clarified, it suggests that the ability to dissect out the role of individual cytokines may be complicated by a variety of factors that can all muddy the waters of cytokine regulation of the disease process. Such factors may include functional redundancy in cytokine action; the fact that individual cytokines may modulate the expression of other cytokines and/or chemokines; cytokine influence may vary at different periods during disease development; and the microenvironment of cytokine production. Though the Th1/Th2 paradigm can relate to aspects of pathogenesis, it is clear that regulatory T cells can prevent type 1A diabetes in animal models and are implicated in humans.^{43,44} The key importance of such regulatory T cells is revealed by children with the IPEX syndrome (immune dysfunction, polyendocrinopathy, enteritis, X-linked) with a mutation of the gene FoxP3, a transcription factor that drives the development of regulatory T cells.⁴⁵

Several caveats should be considered when evaluating animal models. First, no single model exactly replicates the disease process in humans, and genus-specific differences can contribute to this variance. In addition, the highly inbred nature of these models (owing to multiple brother-sister matings) and the controlled housing environment of

these animals implies that the model is not directly analogous to humans, in that inbred mice are monoallelic at all loci. Despite these disadvantages, animal models remain an invaluable tool to research immunopathology.

■ STAGE II: TRIGGERING OF AUTOIMMUNITY (POTENTIAL ENVIRONMENTAL FACTORS) ■

Environmental factors suggested to influence the development of type 1A diabetes include viral infections, bacterial and/or viral superantigens, dietary components and environmental toxins. Many investigators support a viral etiology for type 1A diabetes. However, so far there has been no formal demonstration that viral infections directly cause type 1A diabetes in humans. Congenital rubella (and only congenital infection) is associated with diabetes risk, but such infection increases the risk of a series of autoimmune disorders.

The mechanism by which microbial infections might influence the autoimmune process of type 1A diabetes is poorly defined. Hypotheses include: (1) microbial-specific T and B cells may cross-react with self-antigens (molecular mimicry); (2) virally infected β cells may be directly destroyed by cytotoxic T lymphocytes reacting to viral epitopes displayed on MHC class I; (3) indirect or 'bystander' activation of autoreactive lymphocytes may occur owing to a local increase in inflammatory cytokines associated with viral infection; and (4) the effects of congenital infection (e.g., rubella) on the developing immune system may contribute to disease susceptibility. Without convincing epidemiological evidence for relevant environmental factors, it is difficult to test these hypotheses.

RUBELLA VIRUS

Congenital rubella infection is a well-defined environmental factor contributing to the development of type 1A diabetes in humans. Approximately 12–20% of individuals infected with rubella in utero develop diabetes in 5–20 years, in what appears to be an autoimmune process. One hypothesis to explain this association involves a molecular mimicry mechanism, supported by the fact that there is a shared epitope between a rubella viral noncapsid protein and a 52 kDa islet autoantigen. Alternatively, the rubella virus may alter β -cell antigens as it buds from the membrane, resulting in the formation of a novel antigenic determinant. A separate hypothesis would be that rubella infection might modulate T-cell development and result in abnormal immunologic tolerance to islet and thyroid tissues.⁴⁶

COXSACKIE B VIRUSES

Coxsackie viruses are RNA-containing picornaviruses that have been implicated in the etiology of type 1A diabetes. The Coxsackie viruses are members of the enterovirus class and have six B serotypes (B1–B6). The specific role these viruses play in the etiology of type 1A diabetes has yet to be defined.

Sequence similarity exists between the Coxsackie viral protein 2C (P2-C) and the glutamic acid decarboxylase (GAD65) autoantigen that is expressed in the pancreas. This amino acid sequence homology is highly conserved in Coxsackie B4 isolates, and the relevant peptide has

Table 70.7 Summary of transgenic and knockout studies on the NOD background

been found to bind to HLA-DR3 but not DR4, giving rise to speculation that the molecular mimicry may be limited to the HLA-DR3 subpopulation of type 1A diabetics. In another study, a GAD-peptide AA 247-279 similar to the Coxsackie B virus was shown to stimulate Th1-like lymphocytes derived from children with recent-onset type 1A diabetes. Lymphocytes from these patients were found to have increased IFN- γ mRNA expression, which was not seen in lymphocytes derived from HLA-matched controls.

Attempts to relate antibodies to Coxsackie viruses to the development of type 1A diabetes revealed both positive and negative results.⁴⁷ Because these viruses are ubiquitous in the environment and hence not unique to individuals with type 1A diabetes, it has been difficult to definitively associate viral infection with the disease.⁴⁸ One alternative hypothesis is that a Coxsackie B viral infection may act as a final insult and induce hyperglycemia in individuals who have already lost a substantial amount of β -cell mass.⁴⁹

In addition to the Coxsackie and rubella viruses, numerous other viruses have been implicated in the etiology of type 1A diabetes, including cytomegalovirus, herpes viruses, mumps, retroviruses, rotaviruses, Epstein-Barr viruses and echoviruses.²

MILK PROTEINS

Milk proteins, namely bovine serum albumin (BSA) and casein, have received the most attention as possible dietary components important for the development of type 1A diabetes, and a pilot trial of bovine milk elimination was associated with a decrease in cytoplasmic islet cell antibodies.⁵⁰ Studies from Scandinavia show a correlation between reduction in breastfeeding and an increase in the incidence of type 1A diabetes.⁵¹ Antibodies against BSA have been found in humans, NOD mice and BB rats. One proposed hypothesis is that a peptide of BSA, homologous to the islet antigen ICA-69,⁵² results in the activation of autoimmunity through molecular mimicry. Most of the studies associating the ingestion of milk with the development of diabetes are retrospective and with relatively small effects (odds ratio of 1.6). Importantly, several prospective studies examining the possible association between the expression of anti-islet autoimmunity and early infant exposure to cow's milk in high-risk first-degree relatives failed to find an association.⁵³ Furthermore, in at least one prospective study the duration of breastfeeding did not appear to modulate the development of anti-islet autoimmunity in children at high risk.⁵⁴

STAGE III ACTIVE IMMUNITY

Islet-cell autoantibodies can be detected in sera prior to the development of type 1A diabetes and in new-onset patients prior to insulin therapy.⁵⁵ For three of the autoantigens (glutamic acid decarboxylase (GAD65), insulin and ICA512/IA2) the frequency of positive autoantibody tests is high, and the assays are in a form that allow the testing of thousands of samples (Table 70.8). However, there is no evidence that autoantibodies play a pathogenic role in the immunopathogenesis of type 1A diabetes, and only one study indicating less development of islet autoimmunity for infants with transplacental GAD65 autoantibodies.^{56,57} Evidence against autoantibodies contributing directly to β -cell damage comes from studies of infants born to mothers with type 1A diabetes. Anti-islet autoantibodies of mothers are transferred to the infant transplacentally, yet these infants do not develop disease. As discussed above, the lack of an influence exerted by autoantibodies

does not rule out an important role for B lymphocytes in the pathogenesis of diabetes. Studies from B cell-deficient NOD mice indicate that the development of diabetes is markedly suppressed in such animals, and other studies indicate that transplacental autoantibodies are important in the NOD mouse model.

AUTOANTIGENS/AUTOANTIBODIES

INSULIN

The insulin molecule is the only β cell-specific autoantigen so far associated with type 1A diabetes, and antibodies against insulin are one of the earliest clinical markers of pre-diabetes. Insulin autoantibodies (IAA) can be detected in the sera of approximately 60% of newly diagnosed type 1A patients prior to insulin therapy. The presence of IAA is inversely correlated with age of diabetes onset, with almost 100% of newly diagnosed children less than 5 years of age expressing IAA, compared to less than 20% of those diagnosed after 15 years of age. Moreover, the levels of IAA are associated with the rate of the autoimmune destruction of the β cells, making their detection an important aspect of diagnosis and prevention. Recent studies indicate that insulin autoantibodies are of high affinity when first detected in young infants, and high-affinity insulin autoantibodies are indicators of high risk.

GAD65

Glutamic acid decarboxylase (GAD) is an enzyme that converts glutamate to γ -amino butyric acid (GABA). Two isoforms, GAD65 and GAD67, named for their molecular weights in kilodaltons, have been identified and their expression is not limited to the central nervous system. GAD65 is expressed in human β cells (but is also expressed by α and δ cells of islets) and is a major target autoantigen in type 1A diabetes. Although antibodies to GAD65 can be detected in the sera of 70% of new-onset type 1A patients, only 20% of GAD antibody-positive relatives progress to type 1A diabetes (with long-term follow-up) if no other islet antibodies are expressed.⁵⁸

ICA512 (IA-2)

ICA512 was identified by screening an islet cDNA library with sera from new-onset type 1A diabetics.⁵⁹ The gene encodes a putative tyrosine phosphatase-related molecule expressed in the pancreas (associated with the β -cell secretory granules) and the brain. Despite its homology with tyrosine phosphatase, no enzymatic activity has been demonstrated. The molecule appears to be produced in two alternative splice variants, with the variant lacking the transmembrane exon 13 domain usually termed ICA512 bdc. Autoantibodies usually react with both variants, although approximately 10% of sera from new-onset patients react with one or the other.

The above-mentioned autoantibodies appear in a sequential manner rather than simultaneously, with insulin and GAD65 usually appearing first. This appearance reflects the progression of humoral autoimmunity to β cells, which develops chronically, with early responses often directed against insulin.

Table 70.8 Assays for anti-islet autoantibodies using recombinant antigens

Antigen	Sensitivity (%)	(Specificity) (%)	Comment
Insulin	40–95	(99)	Prevalence inversely correlated with the age of onset
GAD	70	(99)	Prevalence increases with age
ICA512 (IA-2)	60	(99)	Islet tyrosine phosphatase homolog
IA2 β (Phogrin)	55	(99)	These autoantibodies are predominantly a subset of ICA512/IA2/autoantibodies

STAGE IV: LOSS OF INSULIN SECRETION

Given the presence of anti-islet autoantibodies, the loss of first-phase insulin secretion following the administration of intravenous glucose and abnormalities on oral glucose tolerance testing are parameters that aid in defining the time to development of overt diabetes. Prospective studies indicate that identification of risk greatly decreases hospitalization and ketoacidosis.⁶⁰

STAGE V: OVERT DIABETES

By the time overt diabetes develops in humans, most (80–90%) of the β cells are apparently destroyed. In patients who die shortly after the onset of type 1A diabetes, insulinitis can be found within the islets that still contain β cells. After β -cell destruction has occurred in humans and in the various animal models, islets with no β cells remain and the insulinitis resolves. The decrease in β -cell mass accompanying the onset of overt diabetes is associated with a lack of first-phase insulin secretion, which is not restored even if patients are treated with cyclosporine. At the time of diagnosis anti-islet autoantibodies can still be detected in the sera of these patients, and probably reflects the insulinitis and β -cell destruction that is still ongoing. Newly diagnosed type 1A diabetes is often associated with a brief metabolic remission, termed the ‘honeymoon phase’, in which low doses of insulin are required or, in some cases, patients may be transiently insulin independent. This brief metabolic remission usually lasts for less than 1 year. It is likely that this period reflects decreased insulin resistance after treatment of severe hyperglycemia. The ability to induce this temporary remission makes the search for an agent that can maintain long-term remission an important goal.

EFFECTOR MECHANISMS OF β -CELL DESTRUCTION

An important feature supporting the conclusion that type 1A diabetes is an autoimmune disorder is the finding of a lymphocytic infiltrate in the islets. The mechanism by which these cells gain access to the islets and mediate the selective destruction of the insulin-secreting β cells, while leaving other islet cells intact, is still unclear. It is believed by many investigators

that the destruction of β cells occurs through apoptosis in a process that requires B lymphocytes and CD4 and CD8 T lymphocytes. Studies in which B cells or macrophages⁵⁴ are depleted in the NOD model show that these antigen-presenting cells are important in the disease process.

Although some studies have shown that either CD4 or CD8 T cells may, under certain experimental conditions, be sufficient to cause β -cell destruction, it would be difficult to imagine that these cells are acting in isolation. It is more likely that there is a complex interaction between antigen-presenting cells (dendritic cells, macrophages and B cells), T lymphocytes and numerous cytokines that brings about the destruction of the β cells. Studies have supported the role of proinflammatory cytokines, including TNF- α , IL-1, IL-6 and IFN- γ , as well as Fas-FasL interactions, perforin and granzymes and reactive oxygen intermediates (e.g., nitric oxide). Despite numerous reports describing the involvement of many of these molecules, the extent to which each of them participates in β -cell destruction is still controversial.

CD4 T CELLS

CD4 T cells appear to be critical in the pathogenesis of type 1A diabetes. In NOD mice depleted of CD4 T cells using anti-CD4 antibodies, or engineered to be genetically deficient in CD4, diabetes does not develop. Islet-specific T-cell clones have been isolated from the spleen, lymph nodes and islets of Langerhans of NOD mice, and such islet-specific T cells are capable of inducing diabetes after adoptive transfer. Nearly all of these T-cell clones are CD4⁺ and require peptide presentation in the context of the NOD class II I-A^{g7} molecule. Of the CD4⁺ T-cell clones isolated from NOD islets, 55% have been found to be insulin reactive and the remainder reactive with unknown antigens. More than 95% of the insulin-reactive clones recognize a single peptide of insulin which spans the amino acid residues 9–23 of the insulin B chain. This epitope has been termed B9-23, or the B2 peptide. Molecular characterization of the known B9-23 reactive CD4⁺ T-cell clones derived from the NOD islet reveals that the TCR α chain is highly restricted to V α 13 and J α 45 or J α 34.⁶¹ This TCR motif is expressed in up to 60% of insulin-reactive T-cell clones.

CD8 T CELLS

Studies of knockout mice have confirmed the importance of CD8 T cells in islet cell pathology. In β_2 -microglobulin-null NOD mice, which are deficient in CD8 T cells, neither diabetes nor insulinitis occurs. A similar

finding is observed when NOD mice are treated with a monoclonal antibody against CD8. Recently, Wong and colleagues⁶² identified insulin as the autoantigen recognized by a NOD-derived pathogenic CD8 T cell. Interestingly, the region recognized by the CD8 T cells overlapped with the portion of the insulin B chain recognized by the majority of the insulin-reactive CD4 T cells.

Despite the importance of T lymphocytes for the development of type 1A diabetes, both in humans and in animal models, T-cell assays useful for the prediction or follow-up of the diabetes process are essentially nonexistent. It is hoped that with improved knowledge of T-cell autoimmunity better assays will be developed and, for instance, there is evidence that ELISPOT or Tetramer assays can detect autoreactive T lymphocytes,⁶³ but a major limitation is likely to be the frequency of autoreactive T cells outside the islets that are available for study.

HISTOPATHOLOGY

Studies in the NOD model have provided the opportunity to examine the islets at various stages of the natural history of the disease. Through these studies it has become clear that intra-islet infiltration evolves from a stage of peri-insulitis and MHC class I hyperexpression in the NOD islet β cells. The perivascular and periductal T-cell infiltration, termed peri-insulitis, is usually observed at 4–6 weeks of age. Animals at this stage have been described by some authors as being in a state of ‘benign autoimmunity’, in which case the peri-insulitis is thought to be nondestructive. The conversion to invasive insulitis and β -cell destruction (‘malignant autoimmunity’) in these mice was reported to occur abruptly and in an unpredictable fashion as the mice aged. However, O’Brien⁸⁵ and colleagues reported that apoptosis in the NOD islets was detectable throughout the period of peri-insulitis. Apoptotic death of the islets preceded lymphocytic infiltration and then declined when progression to overt diabetes occurred. In another study, NOD mice were observed to have an early increased ‘compensatory’ β -cell proliferation. This was unable to keep pace with the progressive β -cell destruction and resulted in a reduction in β -cell mass that became worse with time and correlated with a decrease in the insulin secretory response.²¹

Histological analyses of the islets in humans have been limited for several reasons, which include the relative inaccessibility of the pancreas for biopsy; the fact that the islets make up only 2–3% of the pancreatic tissue; and the fact that histologic examination of the islets at the time of disease onset (which precedes clinical presentation) has not been possible. Histological evaluation of pancreases from children who have died at disease onset also suggests a slowly evolving autoimmune process in type 1A diabetes.⁴ Foulis and colleagues⁶⁴ have described three histologically distinguishable types of islet in patients with new-onset diabetes: insulin-deficient islets, which make up the largest fraction (approximately 70%); insulin-containing islets with a chronic inflammatory cell infiltrate; and insulin-containing islets that appear normal. T cells make up most of the infiltrate, with CD8 T cells comprising a larger fraction than CD4 in some studies. Butler and colleagues⁶⁵ have described greatly decreased numbers of β cells in pancreases from long-term patients, but nevertheless evidence of β -cell apoptosis.

In contrast to the characteristic peri-insulitis associated with the early stages of immunopathology in the NOD mouse, peri-insulitis does not appear to be a common feature in humans. Another distinction is that insulitis in the NOD mouse is associated with massive mononuclear cell infiltrates not typically seen in humans. The mechanisms that underlie these differences remain unclear. It is, however, a good reminder that the NOD mouse, albeit an excellent model, is clearly not identical to humans.

TYPE 1A DIABETES PREDICTION

By the time a diagnosis of type 1A diabetes is made, approximately 80–90% of the β cells may have been destroyed. Therefore, the ability to predict who will develop type 1A diabetes among high-risk individuals (siblings of type 1A diabetics) has become an important goal. Using HLA haplotype analysis and ‘combinatorial’ autoantibody analyses, clinicians should be able to identify high-risk individuals. Because the autoimmune process in type 1A diabetes begins years before the progression to overt symptoms, the chance of early intervention is feasible. Furthermore, if a definable environmental trigger exists for type 1A diabetes, as it does for celiac disease (wheat gliadin), preventing exposure may be important.

The most important risk factor for disease development is the expression of multiple anti-islet autoantibodies,⁶⁵ particularly two or more of GAD65, ICA512 (IA-2) or insulin autoantibodies (Fig. 70.3). However, there is a subset of relatives who express a single autoantibody, and an even smaller subset expressing multiple autoantibodies, who have the ‘protective’ HLA alleles DQA1*0102, DQB1*0602. In individuals with DQB1*0602 the risk of progressing to diabetes is low, but still present. Approximately 1% (versus 20% of the general population) of patients with type 1A diabetes have this allele.

THERAPEUTIC PRINCIPLES

- >> Autoantibody testing in combination with HLA testing can be used to predict type 1A diabetes.
- >> Insulin therapy is mandatory in type 1A patients who are ketosis prone. Testing of islet cell autoantibodies identifies 10% of adults (thought to have type 2 diabetes) as having type 1A diabetes.
- >> Prevention of diabetic complications is feasible; it requires routine screening for retinal lesions and microalbuminuria.

PREVENTION

IMMUNOSUPPRESSION

The first major trial of general immunosuppressive therapy for newly diagnosed subjects involved the administration of cyclosporine A (CyA).⁶⁶ CyA was effective in prolonging insulin secretion when treatment lasted 1 year and was initiated during the first 6 weeks of insulin therapy. Long-term benefit was limited, however, with relapse of hyperglycemia

Fig. 70.3 Life table analysis of progression to type 1A diabetes in relatives of affected patients subdivided by the number of autoantibodies (GAD65, insulin, ICA512) expressed.

occurring within 3 years despite continued CyA therapy, and despite continued maintenance of improved insulin secretion as measured with C-peptide. When CyA was discontinued, insulin secretion was rapidly lost. Because of the potential for nephrotoxicity and the risk of malignancy associated with long-term treatment, CyA therapy has not been adopted. Other immunosuppressive agents have been studied, including prednisone, anti-CD5, anti-CD25, anti-thymocyte globulin and anti-T12, but so far they have had little success in providing long-term protection. Recent studies of anti-T cell antibodies (in particular modified anti-CD3 antibodies) have shown promise.^{67, 68}

AUTOANTIGEN ADMINISTRATION

The administration of certain islet cell autoantigens, such as insulin and GAD, and derivatives of these autoantigens can prevent diabetes in animal models. For example, in the NOD mouse long-term (up to 1 year) oral ingestion of these autoantigens has been reported to delay the onset and/or reduce the incidence of disease.⁶⁹ Subcutaneous and intranasal administration of the insulin B chain B9-23 can prevent diabetes in the NOD mouse.⁷⁰ Although the precise mechanism by which subcutaneous administration of the insulin peptide mediates immunoprotection is unknown, the isolation of B9-23-reactive CD4 T-cell clones⁷¹ expressing TGF- β suggests that protection may be mediated by regulatory T cells. Much evidence exists that in type 1A diabetes a Th1-dominant response enhances β -cell destruction, whereas a Th2 response is protective. Autoantigen administration appears to dampen the autoimmune response via bystander suppression through the generation of regulatory T cells secreting a Th2 cytokine profile.⁷² In the USA individuals at moderate risk for type 1A diabetes are being randomized to receive either oral insulin or placebo in the Diabetes Prevention Trial-1 (DPT-1). In this same study, individuals at high risk are being randomized to parenteral insulin therapy. Insulin therapy did not overall

decrease progression to diabetes, but there was evidence in a subgroup (those with high levels of insulin autoantibodies) of a significant delay in progression.⁷³

ADJUVANTS

In the NOD mouse a single injection of complete Freund's adjuvant prevents the development of diabetes⁷⁴ but not insulinitis. A single injection of incomplete Freund's adjuvant (IFA) was unable to induce this effect. However, when combined with an injection of B chain of insulin or the B9-23 peptide, IFA was able to prevent diabetes in the NOD mouse.⁷⁰ Vaccination with the bacillus Calmette-Guérin (BCG) strain of *Mycobacterium bovis* has also been found to prevent diabetes in the NOD mouse.⁷⁵ In several randomized double-blinded placebo-controlled trials intradermal BCG vaccination did not alter remission rate or protect β cells.

NICOTINAMIDE

In the NOD mouse large doses of the vitamin nicotinamide delayed the development of diabetes, and preliminary uncontrolled trials suggested that such therapy might also be successful in humans. In light of this, two randomized controlled trials of nicotinamide, the small German DENIS (Deutsche Nicotinamide Trial) trial and the larger ENDIT (European Nicotinamide Trial) trial in Europe, were initiated and no protection was found.⁷⁶

TREATMENT WITH INSULIN

Insulin is administered subcutaneously to millions of individuals with diabetes. Over the past three decades, not only has the purity of the insulin preparations improved, but in developed countries human insulin has essentially replaced the use of porcine or bovine insulin. Porcine insulin differs from human insulin by only one amino acid, whereas bovine insulin differs by three amino acids. Multiple recombinant forms of human insulin and an additional route of administration have been introduced into clinical practice. For fast-acting insulins the change in the insulin molecule disrupts the natural ability of insulin to form hexamers and greatly speeds subcutaneous absorption. Although the insulin is modified, modifications have not been associated with an increase in insulin antibodies or greater immunologic reactions to insulin.

Essentially, all patients treated with insulin, even human insulin, develop a low level of antibodies that cross-react with native insulin. These antibodies are of relatively low affinity compared to the insulin autoantibodies of pre-diabetic patients, and do not usually interfere with insulin action. Insulin resistance due to induced insulin antibodies (defined as patients requiring more than 200 U of insulin per day, and insulin antibodies with a capacity that usually exceeds 50 U of insulin per liter of serum) was always rare and appears to be nearly disappearing as human insulin replaces animal insulins. Allergic or hypersensitivity reactions to insulin and (in the past) lipoatrophy or lipohypertrophy at the site of insulin injection, are also very rare at present. Such allergic reactions can be treated by changing the formulation of insulin used (e.g. NPH insulin to Lente insulin) or, for delayed hypersensitivity, adding small amounts of glucocorticoids to the insulin preparation.

■ ASSOCIATED AUTOIMMUNE DISORDERS ■

Type 1A diabetes is associated with several autoimmune diseases, including Addison's disease, thyroiditis, Graves' disease, pernicious anemia, celiac disease, myasthenia gravis and vitiligo.⁷⁷ The association with other organ-specific autoimmune diseases points to the importance of screening for these diseases in type 1A patients. Several commonly associated diseases or unique syndromes are discussed in this section.

AUTOIMMUNE POLYENDOCRINE SYNDROMES

Polyendocrine syndromes are characterized by multiple autoimmune disorders. Two distinct forms have been described: autoimmune polyendocrine syndrome I (APS-I) and II (APS-II).

Autoimmune polyendocrine syndrome type I (APS-I)

APS-I consists of a triad of chronic mucocutaneous candidiasis, hypoparathyroidism and Addison's disease, which often present in that order. Other endocrine and nonendocrine disorders can also be present or develop later in patients with this syndrome (Table 70.9). Eighteen percent of patients develop type 1A diabetes. APS-I is also known as

autoimmune polyendocrinopathy candidiasis ectodermal dystrophy (APECED), and is an autosomal recessive disorder in which males and females are equally affected. In contrast to APS-II, in which the manifestations of disease usually occur in middle age, APS-I usually manifests in infancy or early childhood. In both syndromes the detection of autoantibodies against endocrine and nonendocrine tissues precedes overt disease.

APS-I is of considerable importance in that it has a defined monogenic etiology. In addition, no association with HLA alleles is found. The gene underlying the pathogenesis of APS-I is localized to the long arm of chromosome 21 (21q22.3) and is termed autoimmune regulator (AIRE).⁷⁸ AIRE has two zinc-finger motifs and a DNA-binding domain, and is localized to the nucleus, suggestive of a role in modulating transcription. Studies by Anderson and colleagues⁷⁹ have led to the hypothesis that the AIRE gene is important for induction of tolerance to 'peripheral' antigens such as insulin, expressed at low levels in the thymus.

Autoimmune polyendocrine syndrome type 2 (APS-II)

APS-II, or Schmidt's syndrome, is the most common of the polyendocrine syndromes and, in contrast to APS-I, the incidence is two to three times higher in females than in males, with onset typically in adulthood. The classic triad of APS-II involves Addison's disease, autoimmune

Table 70.9 Autoimmune polyendocrine syndrome types I and II

	APS-I ^a	APS-II ^b
Inheritance	Autosomal recessive AIRE gene 21q22.3	Autosomal dominant polygenic/oligogenic
HLA association	None	HLA DR3 and DR4
Immunodeficiency	Mucocutaneous candidiasis, asplenism	Not well defined
Age of onset	Infancy or early childhood	Adulthood (peak 20–60)
Sexual prevalence	Equal among males and females	Greater in females (by 2–3-fold)
^a Mucocutaneous candidiasis	73–100%	Not associated
^a Hypoparathyroidism	80–89%	Not associated
^{a,b} Addison's disease	60–72%	70%
^b Type 1 diabetes	4–15%	52%
^b Autoimmune thyroid disease	10–40%	70%
Gonadal failure	38–60% of females 7–14% of males	3.5–10% of females 5–50% of males
Vitiligo	4–9%	4.5%
Hepatitis	10–15%	Rare
Pernicious anemia	12–15%	<1%
Malabsorption	18%	With celiac disease

^aClassic triad for APS-I.
^bClassic triad for APS-II.

thyroid disease and type 1A diabetes, but other endocrine and nonendocrine disorders can be seen in affected patients. Unlike APS-I, APS-II is strongly associated with HLA alleles and susceptibility is probably determined by an interaction between multiple genetic loci and environmental factors. The class II HLA alleles associated with most of the component disorders of APS-II are DR3 (DQB*0201) and DR4 (DQB1*0302).

ADDISON'S DISEASE

Addison's disease, or primary adrenocortical insufficiency, is an autoimmune disease characterized by the presence (in 70% of patients) of autoantibodies directed predominantly against 21-hydroxylase, a key regulator of mineralocorticoid and glucocorticoid synthesis. The myriad clinical manifestations of Addison's disease, including muscle weakness and fatigue, hypotension and hyponatremia, and loss of axillary and pubic hair in women, are the result of cortisol, aldosterone and sex hormone deficiencies, respectively. Addison's disease is the principal component disorder of APS-II.

In 'DR4' patients with Addison's disease DRB1*0404 is the DR4 allele most often carried. Individuals with type 1A diabetes have a 100 times greater risk of developing Addison's disease. This significant increase justifies anti-21-hydroxylase autoantibody screening in type 1A diabetics. The MICA-5.1 allele is an additional major independent determinant of Addison's disease. This nontraditional class I allele has an extra nucleotide that disrupts the transmembrane portion of the molecule.

CELIAC DISEASE

Celiac disease is a common autoimmune disease (incidence of 1 in 250 in the USA) characterized by immune-cell-induced intestinal lesions which may lead to malabsorption and growth failure. The highest incidence occurs in type 1A diabetics and their relatives, with most of these patients expressing DQA1*0501; DQB1*0201 (DR3, DR3/3 or DR5/7).⁸⁰ Of the autoimmune diseases, celiac disease is unique in that intestinal pathology is entirely dependent on the ingestion of cereal proteins, namely wheat, rye and barley. Remarkably, the removal of wheat gliadin from the diet resolves the intestinal lesions and also leads to the disappearance of autoantibodies associated with the disease.

Tissue transglutaminase (tTG), an enzyme that catalyzes the cross-linking of proteins via glutamyl-lysine bonds, has been shown to be the primary autoantigen of the autoantibodies directed to the intestinal tissues (anti-endomysial antibodies).⁸¹ Glutamine residues make up over 40% of the amino acid residues of the gliadin protein, making it a good substrate for transglutaminase. It is postulated that gliadin may become cross-linked to transglutaminase, creating a novel antigenic determinant that is then recognized by T cells.

Tissue transglutaminase IgA antibodies have been assessed using both an enzyme-linked immunoabsorbent assay (ELISA)⁸¹ and a radioisotope-binding assay.⁸² Ten percent of all type 1A diabetics are positive for tTG autoantibodies. Using the radioisotope-binding assay, 22 of 68 (32%) of type 1A diabetics homozygous for HLA-DQ2 express tTG autoantibodies, as opposed to <2% of those lacking DQ2 or DQ8.⁸² Approximately 70% of anti-glutaminase-positive patients have celiac disease on biopsy, and the finding of high serum levels of these antibodies revealed a 100% positive predictive value for biopsy evidence of intestinal lesions.

PITFALLS/CONTROVERSIES

GENERAL POPULATION SCREENING

Current trials that target individuals at increased risk for the development of type 1A diabetes, such as the large multicenter randomized trial headed by the National Institutes of Health (Diabetes Prevention Trial), are aimed at intervening in the pre-diabetic stage with the hope of either delaying or preventing disease onset. The success of such trials relies partly on our ability to reliably detect at-risk individuals (e.g., siblings of affected patients). However, 90% of patients with type 1A diabetes do not have an affected first-degree relative, making prediction in the general population an important goal.

General population screening depends on the development of effective interventions that can be instituted prior to the development of diabetes, and potentially prior to autoimmunity. Given the natural history of type 1A diabetes (for many individuals), this will mean that treatment would need to be initiated in infancy. Further complicating this strategy is that only a subset of genetically susceptible individuals progress to diabetes. This subset is highest (40–50%) for DQ8/DQ2 heterozygous first-degree relatives of patients with type 1A diabetes. Trials can be designed that will determine whether autoantibodies, and subsequently disease, are preventable. Because only 10% of first-degree relatives of patients with type 1A diabetes are DQ8/DQ2 heterozygous, such trials will require the screening of more than 1000 neonates. This is obviously a logistical hindrance to such trials, but the major impediment is likely to be the consideration that antigen-based trials have some probability of activating disease. Thus, it is likely that therapies will initially be evaluated in patients with recent-onset type 1A diabetes, and in individuals expressing autoantibodies and progressing to diabetes, before instituting trials involving individuals with genetic susceptibility alone. Increased knowledge of the basic mechanisms of disease and mechanisms of immunotherapies and new assays that predict efficacy are a high priority, so that safe and effective preventive trials can be carried out.

DISTINGUISHING VARIOUS FORMS OF DIABETES

Not all children presenting with diabetes mellitus have type 1A diabetes. Whereas only 10% of non-Hispanic white children do not express GAD65, ICA512 or insulin autoantibodies, as many as 50% of Hispanic and African-American children do not express these antibodies. For patients with type 2 diabetes oral hypoglycemic agents may be the more appropriate therapy. In such cases, clinicians need to carefully monitor these patients for possible decompensation requiring insulin treatment.

In a fraction of adults presenting with what appears to be type 2 diabetes, anti-islet autoantibodies can be detected.⁸³ When these patients are followed, most eventually require exogenous insulin for control of glycemia. It is likely that such patients, who represent approximately 5–10% of adults presenting with diabetes mellitus, actually have type 1A diabetes. One goal for clinicians is to identify both of the groups described above to ensure that they receive the appropriate therapy in a timely fashion.

Large quantities of antibodies to insulin can occur separately from treatment with insulin as part of the insulin autoimmune syndrome (also termed Hirata syndrome). The two forms of this syndrome, both very rare, are characterized by high-titer anti-insulin antibodies. In the rarest form, monoclonal insulin autoantibodies are produced. The form of the

syndrome with polyclonal anti-insulin autoantibodies is frequently associated with ingestion of sulfhydryl-containing drugs such as methimazole (treatment for Graves' disease) in East Asian patients. In both syndromes hypoglycemia and not insulin resistance is the usual presenting abnormality. The polyclonal syndrome is strongly associated with a specific DRB1 allele (DRB1*0406) and usually resolves with discontinuation of the inciting drug. Ninety-six percent of Japanese patients (48/50) were found to have DR4, and 42 of these had DRB1*0406.⁸⁴

Autoantibodies to the insulin receptor are present in a rare syndrome characterized by both hypoglycemia and hyperglycemia in the same patient at different times. It is thought that the anti-insulin receptor antibodies can act as agonists or antagonists. Patients with this syndrome frequently have systemic autoimmune disorders such as lupus erythematosus, rheumatoid arthritis and Sjögren's syndrome. There are case reports of a favorable response to immunosuppression (e.g., with cyclosporine).

Immunologic lung diseases

Andrew P. Fontenot, Marvin I. Schwarz

71

The lung serves as an interface between the environment and the sanctuary of the body. The defense systems of the upper airways clear the majority of inhaled particulates. Those that evade the upper-airway defenses are combated by the innate and acquired immune responses. Macrophages and lymphocytes are the key cells involved in the initiation and perpetuation of the acquired immune response in the lung. In the normal host, the macrophage is the predominant cell type in bronchoalveolar lavage (BAL). Macrophages serve as scavenger cells, ingesting and degrading the inhaled antigenic load. In addition, these cells serve as antigen-presenting cells for T lymphocytes. Relatively few lymphocytes are present in the normal lung parenchyma. However, after stimulation by the relevant antigen in the surrounding lymphoid tissues, antigen-specific lymphocytes migrate to the lung and participate in the inflammatory response.

Immunologic lung diseases develop when the normal mechanisms of immune self-tolerance fail. Essentially all autoimmune diseases are dependent on the inappropriate activation of autoreactive CD4 T cells as well as autoreactive B cells responsible for the pathogenic autoantibodies. This chapter deals with the pulmonary manifestations of these disorders.

■ IDIOPATHIC INTERSTITIAL PNEUMONIAS ■

The clinical syndromes known collectively as idiopathic pulmonary fibrosis (IPF) or idiopathic interstitial pneumonias comprise a group of histologically distinct disorders. The classical form of IPF has a histological appearance that is now termed usual interstitial pneumonitis (UIP). Other histological and clinical forms include acute interstitial pneumonitis (AIP), desquamative interstitial pneumonitis (DIP), respiratory bronchiolitis-associated interstitial lung disease (RB-ILD), nonspecific interstitial pneumonitis (NSIP), and cryptogenic organizing pneumonia (COP). In order to differentiate between these diseases, a lung biopsy is often required (usually obtained by thoracoscopy). The distinction between these disorders is important since response to treatment and outcome differs.

KEY CONCEPTS

CLASSIFICATION OF THE IDIOPATHIC INTERSTITIAL PNEUMONIAS

- >> The idiopathic interstitial pneumonias comprise a group of seven histologically distinct disorders
- >> The distinction is important since response to treatment and prognosis differs
 - Idiopathic pulmonary fibrosis (IPF) with histopathology labeled as usual interstitial pneumonitis (UIP): the pathology of UIP can occur in other diseases such as collagen vascular diseases
 - Acute interstitial pneumonitis (AIP)
 - Desquamative interstitial pneumonitis (DIP)
 - Respiratory bronchiolitis-associated interstitial lung disease (RB-ILD)
 - Nonspecific interstitial pneumonitis (NSIP)
 - Lymphocytic interstitial pneumonitis (LIP)
 - Cryptogenic organizing pneumonia (COP)
- >> In order to differentiate between these diseases, a thoroscopic lung biopsy is often required

IDIOPATHIC PULMONARY FIBROSIS

The usual form of IPF, also known as cryptogenic fibrosing alveolitis, is the commonest diffuse parenchymal lung disease of unknown etiology.¹ It is characterized by progressive clinical deterioration despite available therapy. Although IPF has characteristic clinical, radiographic, and histologic appearances, other interstitial lung diseases, including the collagen vascular diseases (CVD), drug reactions, and environmental exposures, can mimic these findings. The pathogenesis of IPF remains poorly understood, but current evidence suggests that the disease is mediated through an interplay between immunologic, genetic, and environmental factors.^{2,3}

Clinical manifestations

The incidence and prevalence of IPF remain unknown, although recent studies have reported prevalence rates for men and women as 20.2 per 100 000 and 13.2 per 100 000, respectively.⁴ Both the incidence and prevalence of IPF increase with age, with most patients presenting between 40 and 70 years of age. Although the clinical features of IPF are variable, most patients present with the insidious onset of exertional dyspnea and a dry, nonproductive cough. Physical examination typically reveals dry, end-inspiratory crackles; clubbing may be present in 25–50% of patients.

The chest radiograph typically shows diffuse reticular opacities, predominantly in the lower zone and lung periphery. Ground-glass opacities, small cysts (honeycombing), and reduced lung volumes may also be seen (Fig. 71.1A). These radiographic changes often precede the onset of symptoms, and serial chest radiographs usually reveal progression with associated volume loss. High-resolution computed tomography (HRCT) findings include bibasal peripheral reticular opacities (Fig. 71.1B).⁵ Honeycombing, traction bronchiectasis, and subpleural fibrosis may also be present. The finding of ground-glass opacities on the initial HRCT suggests alveolar inflammation and may identify patients with IPF who are more likely to respond to glucocorticoid therapy.

The typical physiologic abnormalities in IPF are those of a restrictive lung disease with a low diffusing capacity for carbon monoxide and severe gas exchange abnormalities exacerbated by exercise.

Histopathology

The gross appearance of the lungs in IPF shows a nodular pleural surface while histopathologic examination reveals UIP. UIP is characterized by nonuniform and variable distribution of the interstitial changes. At low magnification, alternating zones of interstitial fibrosis, inflammation, honeycombing, and normal lung may be seen (Fig. 71.2A). At higher magnification, findings include derangement of alveolar walls with edema, fibrinous exudate, fibroblast proliferation, and fibrosis. Honeycomb

CLINICAL PEARLS

IDIOPATHIC PULMONARY FIBROSIS (IPF)

- >> IPF is one of the most common causes of diffuse parenchymal lung disease of unknown etiology and is characterized by insidious onset of cough and dyspnea
- >> The histopathologic pattern of IPF is usual interstitial pneumonitis
- >> A confident diagnosis of IPF based on high-resolution computed tomography can only be made in two-thirds of cases
- >> IPF is generally a fatal disorder, characterized by relentless progression and a 5-year survival of 30–50%

Fig. 71.1 Radiographic manifestations of idiopathic pulmonary fibrosis. **(A)** Chest radiograph in a patient with idiopathic pulmonary fibrosis showing diffuse, coarse reticular opacities with a lower-lung zone predominance. Cystic radiolucencies, consistent with honeycombing, are evident. **(B)** High-resolution computed tomography shows peripheral reticular opacities, honeycombing, and traction bronchiectasis.

change refers to enlarged airspaces lined by metaplastic bronchial epithelium and surrounded by walls thickened with collagen (Fig. 71.2B). The earliest finding in UIP is thought to be the “fibroblast focus,” a lesion consisting of distinct clusters of fibroblasts and myofibroblasts in a loose connective tissue matrix within the alveolar wall, with minimal interstitial inflammation or intra-alveolar macrophage accumulation (Fig. 71.2C).⁶ Tables 71.1 and 71.2 compare the clinical and pathologic features of UIP, DIP, RB-ILD, and NSIP.

Pathogenesis

The etiologic agent(s) responsible for the initiation of IPF remains unknown. Evidence suggests that an interaction between genetic, environmental, and viral factors may be involved (Fig. 71.3). Some cases of IPF are familial, inherited as an autosomal dominant trait with variable penetrance.⁷ A recent study suggested that a functionally uncharacterized gene, *ELMOD2*, may be a candidate gene for susceptibility in familial IPF.⁸

At present, the mechanisms involved in the induction of the inflammatory events that lead to the development of lung fibrosis remain poorly understood. However, little doubt exists regarding the immunologic nature of this disease. For example, an identical pathologic process can be seen in several immune-mediated diseases such as CVD, inflammatory bowel disease, and primary biliary cirrhosis. In addition, no single stimulus is responsible for all causes of pulmonary fibrosis. More likely, the fibrotic response represents a final common pathway following certain immune and inflammatory events.

In the normal lung, the interstitium is thin and delicate with few lymphoid cells and fibroblasts. Following the initiation of the inflammatory process, damage to the alveolar epithelium occurs, followed by infiltration of the interstitium with activated immune cells. In addition, immune complexes have been identified in the serum and lungs of IPF patients. Activated alveolar macrophages secrete interleukin-1 (IL-1), IL-8, tumor necrosis factor- α (TNF- α), platelet-derived growth factor (PDGF), and insulin-like growth factor-1 (IGF-1). This cytokine milieu promotes the activation and recruitment of neutrophils and lymphocytes to the area of alveolitis.

T lymphocytes, which accumulate in the alveolar space and interstitium, express an activated phenotype, including the expression of human leukocyte antigen (HLA)-DR and IL-2 receptor. Following activation, CD4 T cells evolve into two major subsets distinguished by the cytokines produced (Chapters 10 and 17).⁹ In IPF, T cells expressing a Th2-type phenotype predominate, producing IL-4, IL-5, IL-10, and IL-13. Th2 cells are mainly involved in the development of humoral immunity by helping B cells through the promotion of class switching and enhancement of the production of certain IgG isotypes and production of IgE. Evidence suggests that a switch to Th2-type cells may be important in the development of fibrosis through the deposition of matrix components. Thus, a switch to Th2-type cells may occur in IPF followed by the release of Th2-type cytokines stimulating production of extracellular matrix as well as attracting the influx of fibroblasts.

In addition to their role as scavengers, alveolar macrophages are vital in the repair phase of inflammation. However, the distinguishing feature between a self-resolving inflammatory process and a fibrotic response, as seen in IPF, is the accumulation of collagen. Current evidence suggests that the fibrotic process in IPF is a consequence of dysregulation of both collagen synthesis and degradation. Macrophage-derived growth factors, including transforming growth factor- β (TGF- β), PDGF, and IGF-1,

Fig. 71.2 Histopathology of usual interstitial pneumonia (UIP). **(A)** Low-magnification photomicrograph of UIP showing the variegated appearance from one field of view to the next with areas of dense subpleural fibrosis (arrows) separated from other areas of normal lung. **(B)** High-magnification photomicrograph of UIP showing honeycomb change characterized by enlarged airspaces filled with mucin and separated by fibrosis. **(C)** Fibroblast focus in UIP is characterized by clusters of spindle-shaped fibroblasts (arrow) in a loose connective tissue matrix within the alveolar wall.

Table 71.1 Clinical features of the idiopathic interstitial pneumonias

	UIP	DIP	RB-ILD	AIP	NSIP
Mean age (years)	57	42	36	49	49
Childhood	No	Rare	No	Rare	Occasionally
Onset	Insidious	Insidious	Insidious	Acute	Subacute, insidious
Mortality (mean survival)	68% (5–6 years)	27% (12 years)	0%	62% (1–2 months)	11% (17 months)
Response to steroids	Poor	Good	Good	Poor	Good
Recovery possible	No	Yes	Yes	Yes	Yes

AIP, acute interstitial pneumonitis; DIP, desquamative interstitial pneumonitis; NSIP, nonspecific interstitial pneumonitis; RB-ILD, respiratory bronchiolitis-associated interstitial lung disease; UIP, usual interstitial pneumonitis.

Table 71.2 Histopathologic features of the idiopathic interstitial pneumonias

	UIP	DIP/RB-ILD	AIP	NSIP
Temporal appearance	Variegated	Uniform	Uniform	Uniform
Interstitial inflammation	Scant	Scant	No	Prominent
Collagen/fibrosis	Patchy	Diffuse (DIP) Focal (RB-ILD)	No	Diffuse
Fibroblast proliferation	Fibroblast foci prominent	No	Diffuse	Rare
BOOP	No	No	No	Focal
Honeycomb change	Yes	No	No	Rare
Intra-alveolar macrophages	Focal	Diffuse (DIP) Focal (RB-ILD)	No	Patchy
Hyaline membranes	No	No	Focal	No

AIP, acute interstitial pneumonitis; BOOP, bronchiolitis obliterans organizing pneumonia; DIP, desquamative interstitial pneumonitis; NSIP, nonspecific interstitial pneumonitis; RB-ILD, respiratory bronchiolitis-associated interstitial lung disease; UIP, usual interstitial pneumonitis.

Adapted from Katzenstein AL, Myers JL. Idiopathic pulmonary fibrosis: clinical relevance of pathologic classification. *Am J Respir Crit Care Med* 1998; 157: 1301.

stimulate fibroblast proliferation and collagen deposition.¹⁰ Adequate resolution of an inflammatory process requires matrix degradation. Metalloproteases produced by macrophages and fibroblasts are involved in matrix degradation, and control of metalloprotease production involves substances known as tissue inhibitors of metalloproteases (TIMPs). TIMPs are elevated in the lungs of patients with IPF. In addition, TGF- β can markedly augment TIMP production. Thus, there appears to be a loss of balance between the events mediating resolution and those mediating perpetuation of the inflammatory response, setting the stage for lung injury, tissue remodeling, and the development of irreversible pulmonary fibrosis.¹¹

Diagnosis

The diagnostic evaluation of a patient with diffuse parenchymal lung disease includes a thorough history and physical examination with particular attention to symptoms and signs that could indicate CVD, occupational and environmental exposures, or medication and drug usage. A careful family history is also important.

The history and physical findings in IPF are nonspecific. However, extrapulmonary involvement does not occur: the presence of fever, arthralgias, myalgias, or pleuritis should suggest a collagen vascular disorder. Antinuclear antibodies and rheumatoid factor are present in

KEY CONCEPTS

PATHOGENESIS OF THE IDIOPATHIC INTERSTITIAL PNEUMONIAS

- >> Although the inciting event(s) is unknown in the different diseases, a common result is a dysregulated fibroproliferative response (similar to wound healing), which leads to excessive extracellular matrix production and lung remodeling
- >> A genetically determined inability to repair and re-epithelialize the denuded basement membranes adequately may be a contributing factor and may relate to the familial occurrence of some cases of idiopathic pulmonary fibrosis
- >> The presence of a chronic stimulus (autoantigen), as is seen in the pneumoconioses, may result in a persistent inflammatory and immune response and lead to a failure in the normal healing process
- >> The release of transforming growth factor- β following epithelial injury stimulates collagen synthesis and the prevention of apoptosis of proliferating fibroblasts in the lung and may impair collagen degradation by inhibiting the production of metalloproteases
- >> A predominant Th2 response in the lung and the absence of interferon- γ favor the development of a fibrotic response

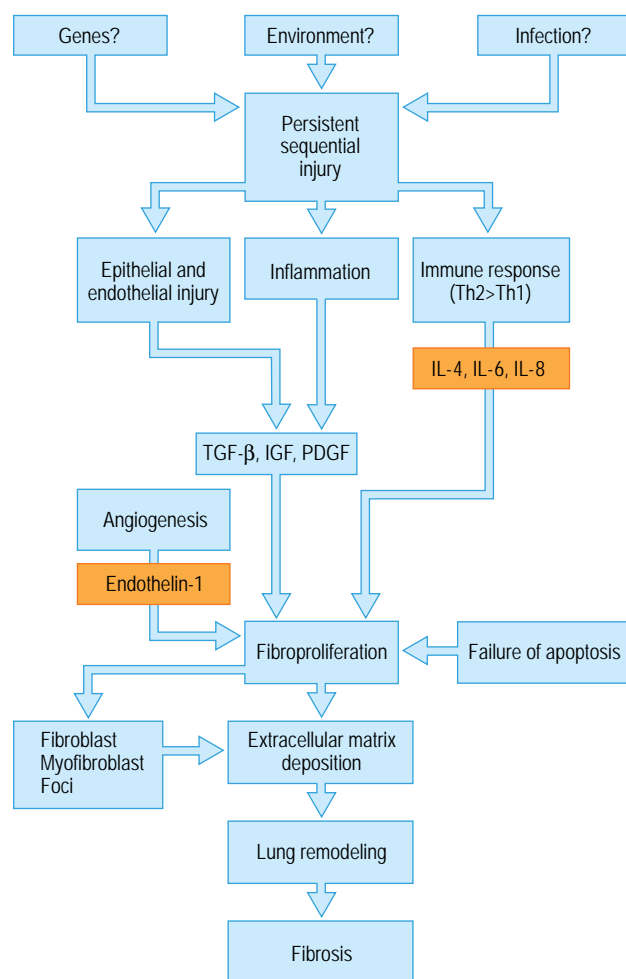

Fig. 71.3 Events hypothesized to be involved in the pathogenesis of idiopathic pulmonary fibrosis. The initiating event(s) leading to persistent lung injury remains poorly understood. The interaction between genetic factors, environmental exposures, and infectious agents leads to epithelial and endothelial injury, resulting in the secretion of macrophage-derived growth factors, including transforming growth factor- β (TGF- β), insulin-like growth factor-1 (IGF-1), and platelet-derived growth factor (PDGF). This cytokine milieu stimulates fibroblast proliferation and collagen deposition. In addition, the resulting Th2 immune response stimulates extracellular matrix production and fibroblast proliferation, resulting in lung remodeling and, eventually, lung fibrosis.

10–20% of IPF patients, but titers greater than 1:160 should suggest the possibility of an alternative diagnosis.

The majority of patients with IPF have an abnormal chest radiograph at the time of presentation. Basal peripheral reticular opacities are the characteristic radiographic findings of IPF. A confident diagnosis of IPF from HRCT of the lung requires the presence of patchy, peripheral bibasal reticular abnormalities.¹² The presence of extensive ground-glass opacities on HRCT should suggest an alternative diagnosis, such as DIP,

hypersensitivity pneumonitis, bronchiolitis obliterans organizing pneumonia (BOOP), or NSIP.

A surgical lung biopsy is recommended in suspected IPF patients without a definitive HRCT appearance and who do not have contraindications to the procedure. This is especially important in patients with atypical clinical or radiographic findings, which could suggest the possibility of one of the other histologic patterns of the idiopathic interstitial pneumonias and an improved prognosis. Biopsy may be omitted in elderly patients with cardiovascular disease, or those with evidence of extensive honeycomb change. Video-assisted thoracoscopic (VATS) biopsy is the preferred surgical technique and has been associated with less morbidity and a decreased hospital stay compared with open lung biopsy.

Treatment and outcome

The usual course of IPF is relentless progression without spontaneous remission, commonly with a fatal outcome. Recent studies in patients with biopsy-proven IPF indicate a shorter survival than previously thought (30–50% 5-year survival). Currently available treatment options include glucocorticoids or immunosuppressant drugs, either alone or in combination. However, despite the fact that the glucocorticoids are considered the mainstay of therapy for IPF, no prospective, randomized, double-blind, placebo-controlled trial has demonstrated their efficacy in the treatment of IPF. Moreover, a recent study showed that the combination of prednisone and cyclophosphamide did not alter survival of IPF patients.¹³ Thus, there is no good evidence to support the use of any specific therapy in the management of IPF. Large controlled trials are under way to confirm the potential usefulness of newer agents such as IFN- γ _{1b},¹⁴ pirfenidone, and

THERAPEUTIC PRINCIPLES

TREATMENT OF PATIENTS WITH IDIOPATHIC PULMONARY FIBROSIS (IPF)

- >> No data exist to show that any currently available therapy alters survival and improves quality of life
- >> Therapy is not recommended in all IPF patients (e.g., age >70 years, end-stage honeycomb lung, and significant comorbid diseases such as cardiac disease or diabetes mellitus)
- >> Until studies define the best therapeutic regimen in IPF, combined therapy should include prednisone 0.5 mg/kg per day for 4 weeks followed by a taper to 0.125 mg/kg per day plus azathioprine or cyclophosphamide 2mg/kg per day
- >> At least 3 months are needed to determine an objective response to any intervention

bosentan. Lung transplantation should be considered in patients with progressive clinical and physiologic deterioration who meet established criteria. Early listing is crucial since the waiting time may exceed 2 years.

The most common cause of death in patients with IPF is progression of the underlying disease.¹⁵ In one study, 39% of IPF patients died of respiratory failure, with cardiovascular complications (ischemic heart disease, heart failure, stroke) accounting for 27% of the deaths. Other causes of death in IPF include bronchogenic carcinoma (10%), infection (7%), and pulmonary embolism (3%).

ACUTE INTERSTITIAL PNEUMONIA

Acute interstitial pneumonia (AIP) is a fulminant form of idiopathic interstitial pneumonia. Although it was previously thought to represent an acute phase of UIP, recent studies indicate that it may be a distinct entity. However, in patients with documented UIP/IPF, acute exacerbations may demonstrate the pathology of AIP superimposed on the features of UIP.

Clinical manifestations

AIP usually presents with acute onset of dyspnea followed by rapid progression to respiratory failure. The clinical, radiographic, physiologic, and histologic features are identical to those of the adult respiratory distress syndrome but without any identifiable cause. Most patients are previously healthy individuals over 40 years of age. Men and women are equally affected. A viral prodrome is common, with symptoms including fever, nonproductive cough, and dyspnea. Laboratory studies are nonspecific. Chest radiographs show diffuse, bilateral airspace opacities, and on HRCT there is ground-glass attenuation. A similar presentation may complicate or represent the initial manifestation of a CVD.

Histopathology

AIP is characterized by diffuse interstitial fibrosis that is temporally uniform (Fig. 71.4).¹⁶ The changes are identical to the organizing phases of diffuse alveolar damage, as seen in ARDS. Within the thickened

Fig. 71.4 Histopathology of acute interstitial pneumonitis. Diffuse thickening of the alveolar septum with an infiltration of mononuclear cells is the characteristic abnormality. The temporal uniformity of this process is also apparent.

interstitial space, there is active, diffuse fibroblast proliferation similar to the focal fibroblast foci seen in UIP. If this is progressive, honeycomb change occurs. However, these airspaces are lined with alveolar epithelium as opposed to the bronchiolar epithelium lining honeycomb spaces. Other features of acute lung injury, which are frequently seen in AIP, are intra-alveolar hyaline membranes.

Diagnosis

The diagnosis of AIP requires a clinical syndrome of idiopathic ARDS and the presence of organizing diffuse alveolar damage on lung biopsy. Thus, an openlung biopsy or VATS lung biopsy is suggested to secure the diagnosis and exclude other causes of acute interstitial lung disease.

Treatment and outcome

No effective therapy exists for patients with AIP. Glucocorticoids are utilized in most cases, but no survival benefit has been shown. One study shows that the additional use of anticoagulation improves survival. Overall, the prognosis of patients with AIP is poor, with mortality rates ranging from 50% to 88%. Half of patients die within 6 months of disease onset. However, those individuals who survive may have complete recovery of lung function. Once recovered, AIP rarely recurs.

DESQUAMATIVE INTERSTITIAL PNEUMONITIS

DIP represents fewer than 3% of all cases of interstitial lung disease.¹⁷ However, it is a distinct clinicopathological entity that differs substantially from UIP.

Clinical manifestations

DIP affects individuals in their fourth to fifth decades of life; a male predominance is noted in most studies. This disease occurs predominantly in cigarette smokers. Clinically, most individuals present with

Fig. 71.5 Radiographic manifestations in desquamative interstitial pneumonitis. High-resolution computed tomography in a patient with desquamative interstitial pneumonitis shows ground-glass attenuation in the periphery of the upper and lower lung fields.

Fig. 71.6 Histopathology of desquamative interstitial pneumonitis. A high-magnification photomicrograph of desquamative interstitial pneumonitis shows the uniform, diffuse accumulation of macrophages within the alveolar space with associated thickening of the alveolar septum. These aggregates of macrophages almost completely fill the alveolar spaces.

subacute onset of a dry, nonproductive cough and dyspnea. Clubbing is present in approximately 50% of DIP patients. Laboratory evaluation is usually nonspecific.

The chest radiograph typically reveals bibasal ground-glass opacities that are not disease-specific. Reticulonodular interstitial infiltrates have also been reported. In addition, a normal chest radiograph may be seen in up to 20% of symptomatic individuals. HRCT confirms the chest radiograph findings, showing ground-glass attenuation in the periphery of the lower lung zones (Fig. 71.5). Pulmonary function testing shows a restrictive defect with an associated decreased diffusing capacity and hypoxemia.

Histopathology

DIP is a misnomer. It was initially thought that the intra-alveolar cells represented sloughed or desquamated alveolar epithelial cells. However, DIP is pathologically characterized by uniform, diffuse accumulation of macrophages in the alveolar space (Fig. 71.6).¹⁶ At low magnification, the overall appearance is one of uniformity from one field of view to the next as opposed to the variegated appearance of UIP. In addition, scant interstitial inflammation with varying degrees of fibrosis of the alveolar septum is present.

Diagnosis

The diagnosis of DIP requires tissue confirmation of the pathologic lesion. This is important since this process has a better prognosis and response to therapeutic intervention compared to IPF. A DIP-like lesion is frequently seen in the other idiopathic interstitial pneumonias as well as in eosinophilic granuloma, drug reactions, and other unrelated conditions. Thus, the diagnosis of DIP requires careful correlation of pathologic findings with clinical and radiologic findings.

Treatment and outcome

The primary intervention in DIP is smoking cessation. Since there are a limited number of cases, it is unclear whether glucocorticoids alter the natural history of this disease. A mortality rate of 28% with a mean survival of 12 years was initially reported, compared to a 66% mortality and a mean survival of 5.6 years in UIP. Of note, 22% patients improved spontaneously and 60% responded to glucocorticoid therapy. This improvement is dramatically different from IPF, in which spontaneous improvement rarely, if ever, occurs and a response to glucocorticoids is seen in only 10–15% of patients. There are, however, a number of patients with DIP who fail to respond to treatment and progress to respiratory failure, secondary to advanced fibrosis.

RESPIRATORY BRONCHIOLITIS-ASSOCIATED INTERSTITIAL LUNG DISEASE

RB-ILD is a distinct clinical entity that occurs in current or former cigarette smokers. However, it remains unclear whether RB-ILD and DIP represent different diseases or different ends of the spectrum of the same disease process.¹⁷ DIP occurs predominantly and RB-ILD occurs exclusively in cigarette smokers, suggesting a common pathogenesis related to cigarette smoke.

Clinical manifestations

In the two studies to date evaluating RB-ILD, the mean age at presentation was 36 years. A male predominance was noted, and all individuals with RB-ILD were cigarette smokers. The most common symptoms were a dry, nonproductive cough and dyspnea. Clubbing is absent in RB-ILD, in contrast to its frequent presence in patients with DIP.¹⁸ Laboratory evaluation is nonspecific.

The chest radiograph typically shows diffuse, fine reticular or nodular interstitial opacities with normal lung volumes. Additional findings include bronchial wall thickening and a prominent peribronchovascular interstitium. HRCT may reveal ground-glass opacification as well as emphysema.

Pulmonary function tests most commonly reveal a mixed restrictive–obstructive pattern with a reduced diffusing capacity and mild hypoxemia. An isolated elevation of the residual volume may also be observed.

Histopathology

The pathology of RB-ILD has similarities to DIP. However, in RB-ILD, the intra-alveolar macrophages accumulate primarily within the peribronchiolar airspaces and are associated with thickening of the alveolar septum in these areas (Fig. 71.7). The differentiation of this lesion from DIP requires sparing of distal airspaces with the lesion confined to the peribronchiolar airspaces in RB-ILD.

Diagnosis

RB-ILD should be suspected in young individuals with a history of cigarette use who complain of cough and dyspnea with a chest radiograph or HRCT showing nodular and/or reticular interstitial opacities. The diagnosis requires tissue confirmation of the pathologic findings noted above.

Treatment and outcome

The key therapeutic intervention in RB-ILD is cessation of smoking. The use of glucocorticoids has been associated with favorable results. At present, the clinical course and prognosis of patients with RB-ILD are unknown. In most clinical series, patients either improved or stabilized with no deaths reported.

Fig. 71.7 Histopathology of respiratory bronchiolitis – interstitial lung disease. An ectatic bronchiole with a thickened wall is shown, with a mononuclear infiltrate extending into the immediately surrounding alveoli.

NONSPECIFIC INTERSTITIAL PNEUMONITIS

The term NSIP was first used to describe cases of interstitial pneumonia that did not demonstrate a pattern of UIP, AIP, or DIP.¹⁹ Currently, the term NSIP is applied to an idiopathic interstitial pneumonia or to a similar histologic pattern that occurs in CVD, hypersensitivity pneumonitis, or drug-induced lung disease. In fact, 16% of patients in the original description of NSIP had one of the CVD.¹⁹

Clinical manifestations

Idiopathic NSIP is most often seen in middle-aged individuals, and a slight female predominance has been noted.²⁰ A dry, nonproductive cough and exertional dyspnea are the most common symptoms, although fever is present in 25% of patients. Symptoms are usually present for 6–10 months prior to diagnosis. As in other interstitial pneumonias, the laboratory evaluation is nonspecific.

The chest radiograph usually shows bilateral interstitial infiltrates and sometimes can be normal in a symptomatic patient. The HRCT characteristically shows bilateral, patchy ground-glass attenuation indistinguishable from DIP or RB-ILD.⁵

Histopathology

NSIP is characterized by varying but temporally uniform degrees of fibrosis and inflammation of the alveolar septum, without histopathologic features indicative of UIP, AIP, or DIP (Fig. 71.8). Katzenstein and Fiorelli¹⁹ divided NSIP cases into three groups depending on the presence or absence of interstitial fibrosis: interstitial lymphoplasmacytic inflammation (48% of cases); inflammation and fibrosis (38%); and fibrosis (14%). Although the changes are temporally uniform, they may be patchy with intervening areas of normal lung.

This temporal uniformity is in contrast to the variegated pattern seen in UIP. Fibroblast foci, the earliest lesion seen in UIP, are found in 20%

Fig. 71.8 Histopathology of nonspecific interstitial pneumonitis. Low-magnification photomicrograph of cellular nonspecific interstitial pneumonitis shows diffuse uniform thickening of the alveolar septum due to the presence of a lymphoplasmacytic infiltrate.

of patients with NSIP, making the differentiation of fibrotic NSIP from UIP difficult. The key feature in this circumstance is the temporal uniformity of the lesion in NSIP.

Treatment and outcome

Unlike patients with UIP, individuals with NSIP have a favorable prognosis. In the original description of the disease, 45% of subjects completely recovered while another 42% remained stable or improved.¹⁹ Only 11% of patients died, with a mean survival of 16 months. All of the individuals with an aggressive course were in the fibrotic group. Ten-year survival in the cellular group was 90%, compared to 35% in patients with the fibrotic pattern. Despite the worse prognosis of NSIP with a fibrosing pattern, this is still significantly better than the 10-year survival rate of UIP patients (15%).²¹

CRYPTOGENIC ORGANIZING PNEUMONIA

COP or idiopathic BOOP is a specific clinicopathologic disorder of unknown etiology characterized by excessive proliferation of granulation tissue within the lumen of the distal airspaces.²² The term COP is reserved for cases demonstrating BOOP without an obvious cause, since this histologic appearance also occurs in a variety of inflammatory lung disorders, including CVD, malignancy, infections, and those caused by medications.

Clinical manifestations

The onset of disease is usually in the fifth to sixth decades of life; men and women are affected equally. Most individuals have symptoms for less than 2 months prior to diagnosis. The initial presentation is characterized by a dry, nonproductive cough with flu-like symptoms, including fever, sore throat, and malaise. This is followed by progressive dyspnea and cough. Routine laboratory evaluation is nonspecific.

The chest radiograph is characterized by diffuse, often patchy alveolar opacities in the setting of normal lung volumes (Fig. 71.9A). These opacities can be migratory and can have a peripheral distribution similar to those seen in chronic eosinophilic pneumonia. Other rare radiographic manifestations include linear or nodular interstitial opacities and honeycombing. The presence of a pleural effusion or pleural thickening should suggest an associated CVD.

HRCT of the chest shows patchy airspace consolidation more commonly located in the lung periphery with a lower-lung zone predominance (Fig. 71.9B). Other findings include ground-glass attenuation, small nodular opacities, and bronchial wall thickening.

As in other interstitial lung diseases, a restrictive ventilatory defect is the most common pulmonary function abnormality. Gas exchange abnormalities are common and are accompanied by decreased diffusing capacity, widening of the alveolar–arterial gradient, and exercise-induced hypoxemia.

Histopathology

The histopathology of COP is characterized by excessive proliferation of granulation tissue in the small airways and alveolar ducts with associated chronic inflammation in the alveolar walls (Fig. 71.10).²³ The intraluminal

fibrotic buds (Masson bodies) consist of loose collagen-embedding fibroblasts and myofibroblasts and have a tendency to extend from one alveolus to the next, giving a characteristic “butterfly” pattern. The lesions are patchy in nature and have a uniform temporal appearance at low magnification with preservation of the underlying lung parenchyma. COP has been described as the prototypical healing response of the lung to a variety of insults.

Fig. 71.9 Radiographic findings in cryptogenic organizing pneumonia. **(A)** Chest radiograph in a patient with cryptogenic organizing pneumonia shows bilateral patchy alveolar opacities with a peripheral distribution in the setting of normal lung volumes. **(B)** Chest computed tomography shows a dense right lower lung consolidation with the presence of air bronchograms.

Fig. 71.10 Histopathology of cryptogenic organizing pneumonia. A photomicrograph of cryptogenic organizing pneumonia shows intra-alveolar fibroblast proliferation (arrows) and early collagen production. In addition, thickening of the alveolar septa with a lymphoplasmacytic infiltrate consistent with cellular nonspecific interstitial pneumonitis is present.

Diagnosis

The presence of BOOP in a lung biopsy does not necessarily represent COP since this is a diagnosis of exclusion. Organizing pneumonia is a nonspecific response to many lung injuries and may occur in conjunction with another pathologic process or as a component of other primary pulmonary disorders such as infections, irradiation, CVD, hypersensitivity pneumonitis, Wegener's granulomatosis (WG), or chronic eosinophilic pneumonia (Table 71.3).

Treatment and outcome

Treatment with glucocorticoids usually offers dramatic clinical and radiographic improvement within days to weeks.²³ Complete clinical, physiologic, and radiographic recovery occurs in two-thirds of cases. However, in the remainder, persistent disease with progression to fibrosis can be expected. It is common for relapses to occur with glucocorticoid tapering, followed by improvement with reintroduction of treatment; consequently at least 6 months of therapy is recommended. The 5-year survival in COP is 73%, compared to 5-year survival rates of 44% in patients with BOOP due to other causes (e.g., CVD) or 30% for IPF.

VASCULITIS

The primary systemic vasculitides are a heterogeneous group of disorders of unknown etiology with a wide spectrum of clinical manifestations (Chapter 58). The complexity of the clinical and histopathologic features, as well as the potential for overlap, can make specific diagnosis difficult. The 1992 Chapel Hill International Consensus Conference was convened to reconcile definition and classification schemata.²⁴ This nomenclature is based on histopathologic criteria including size of vessels

Table 71.3 Disorders associated with a bronchiolitis obliterans organizing pneumonia (BOOP) pattern

Idiopathic BOOP (cryptogenic organizing pneumonia)

Collagen vascular diseases

- Systemic lupus erythematosus
- Rheumatoid arthritis
- Polymyositis/dermatomyositis
- Sjögren syndrome

Hypersensitivity pneumonitis

Chronic eosinophilic pneumonia

Drug-induced

- Gold
- Penicillamine
- Amiodarone
- Bleomycin
- Sulfa drugs

Wegener's granulomatosis

Bone marrow transplantation

Lung transplantation/rejection

Inhalational injury

Neoplasms

Lung irradiation

Virus-associated

- Human immunodeficiency virus (HIV)
- Influenza
- Adenovirus

involved and the presence or absence of serum anti-neutrophil cytoplasmic antibody (ANCA).

Most of the pulmonary vasculitides are systemic in nature. Consequently, the lung is one of many organ systems involved in the disease process. The systemic vasculitides, which typically involve the small vessels of the lung, include WG, Churg–Strauss syndrome (CSS), and microscopic polyangiitis. Involvement of alveolar capillaries (pulmonary capillaritis) in the inflammatory process results in intra-alveolar bleeding and the clinical syndrome known as diffuse alveolar hemorrhage (DAH).

WEGENER'S GRANULOMATOSIS

WG (Chapter 58) is a systemic vasculitis of small arteries and veins involving the upper and lower respiratory tract, often with associated glomerulonephritis. A limited form of WG involving only the upper and lower respiratory tract has been observed in 28% of patients.²⁵ Classically, the inflammatory lesions include necrosis, granulomatous inflammation, and vasculitis.

Clinical manifestations

The incidence of WG is unknown. Men and women are affected equally; the mean age at presentation is 40 years, with approximately 15% of patients presenting prior to the age of 19 years. The clinical presentation is characterized by upper respiratory tract signs and symptoms, including recurrent epistaxis, mucosal ulcerations, and septal perforation. At initial presentation, 90% of patients have evidence of upper

CLINICAL PEARLS

LUNG INVOLVEMENT IN WEGENER'S GRANULOMATOSIS (WG)

- >> WG is a small-vessel vasculitis involving the upper and lower respiratory tracts and associated with glomerulonephritis
- >> Although 15% of patients are diagnosed prior to the age 19 years, the mean age at presentation is 40 years
- >> In the setting of limited WG, the sensitivity of cytoplasmic anti-neutrophil cytoplasmic antibody (c-ANCA) is only 65%
- >> The lung histopathology is characterized by vasculitis, necrosis, and granulomatous inflammation
- >> The histopathologic correlate of diffuse alveolar hemorrhage in WG is capillaritis

and lower respiratory tract involvement. The most frequent lower respiratory symptoms are cough, dyspnea, and hemoptysis. DAH is an uncommon presenting manifestation of WG, occurring in 5% of patients. Only 18% of patients have renal involvement at initial presentation, but 75% will go on to develop glomerulonephritis within 2 years of presentation. Other nonspecific findings include fever, malaise, and weight loss.

Laboratory findings in WG include elevated erythrocyte sedimentation rate, mild anemia, leukocytosis, and thrombocytosis. c-ANCA, an autoantibody directed against a neutrophil cytoplasmic serine protease, proteinase 3, is highly specific (> 95%) for WG. The sensitivity of c-ANCA parallels disease activity and may be as low as 65–70% in patients with inactive disease. In limited WG, the sensitivity of the c-ANCA is only 65%. Thus, a negative c-ANCA in the setting of limited WG does not exclude the diagnosis.

The most common radiographic findings in WG are single or multiple pulmonary nodules with or without cavitation.²⁶ Less common findings include pleural effusions, bilateral alveolar opacities representing DAH, hilar adenopathy, and the presence of an aspergilloma in a pre-existing cavity. Occasionally, endobronchial involvement can cause lobar atelectasis.

Histopathology

The pulmonary histopathology of WG is characterized by vasculitis, parenchymal necrosis, and granulomatous inflammation, accompanied by a mixed infiltrate of neutrophils, lymphocytes, histiocytes, and eosinophils.²⁷ The necrotizing granulomas vary from punctate microabscesses to large geographic zones of necrosis, while the vasculitis typically involves pulmonary arteries, veins, and capillaries.

The histopathologic correlate of DAH in WG is pulmonary capillaritis. Even though the frequency of this manifestation of WG is low, capillaritis was observed in 35% of granulomatous lesions, usually adjacent to the granulomatous process.

The renal histopathology in WG shows a focal, segmental necrotizing glomerulonephritis with or without crescent formation (Chapters 58 and 67). This lesion is not specific for WG as it also occurs in other small-vessel vasculitides and Goodpasture syndrome.

Treatment and outcome

The recommended therapy for WG consists of cyclophosphamide (2 mg/kg per day) and prednisone (1 mg/kg per day). The prednisone dosage is tapered once remission is achieved; cyclophosphamide is continued for 6–12 months after the disappearance of symptoms and gradually tapered over the next several months.

With this regimen, a partial remission can be achieved in 90% of patients and a complete remission occurs in 75% patients.²⁸ Approximately 50% of patients who experience a complete remission suffer one or more relapses. Although this regimen has converted a previously fatal disease into a treatable disorder with prolonged survival and often a cure, it is associated with significant toxicity. Treatment-related side effects include infections, hemorrhagic cystitis, bladder cancer, and myelodysplasia. The increased incidence of *Pneumocystis jiroveci* pneumonia in patients with WG has led to the recommendation that all WG patients who are receiving daily glucocorticoids should be given chemoprophylaxis against *P. jiroveci*.²⁸ The elimination of B cells via treatment with anti-CD20 monoclonal antibody has been attempted with success, warranting the performance of clinical trials.²⁹

CHURG-STRAUSS SYNDROME

CSS, previously referred to as allergic angiitis and granulomatosis, is a rare disorder characterized by allergic rhinitis, asthma, eosinophilia, and a granulomatous vasculitis.³⁰ The lung is the most common organ affected. The diagnosis is sometimes unclear due to similarities with other vasculitides, such as WG.

Clinical manifestations

The incidence and prevalence of CSS are unknown. The mean age at diagnosis is 38 years; men and women are affected equally. In most cases there are three phases of the disease. The prodromal phase is characterized by atopy (rhinitis and asthma) and occurs during the second and third decades of life. This is followed by the eosinophilic phase with peripheral blood eosinophilia and eosinophilic tissue infiltration, including chronic eosinophilic pneumonia. Finally, the vasculitic phase is heralded by the onset of life-threatening vasculitis affecting medium and small vessels. This classic presentation is not universal, and, in 20% of cases, asthma, eosinophilia, and vasculitis develop simultaneously.

Asthma and allergic rhinitis are the most consistent nonvasculitic findings in CSS. Complications related to vasculitis include skin changes in two-thirds of patients, manifesting as subcutaneous nodules and palpable purpura. The most common neurologic complication is a peripheral neuropathy due to mononeuritis multiplex. Cardiovascular involvement includes pericarditis, coronary arteritis, and eosinophilic myocarditis, and accounts for approximately 50% of the deaths due to CSS. Renal involvement is more common than previously reported, with one study showing some degree of renal involvement in approximately 90% of patients.

Laboratory tests are nonspecific, but abnormalities include peripheral blood eosinophilia ($5-10 \times 10^9/L$), anemia, leukocytosis, and an elevated erythrocyte sedimentation rate. Approximately 50% of CSS patients are p-ANCA-positive, usually with autoantibodies to myeloperoxidase. BAL shows eosinophilia, but this is nonspecific.

The chest radiograph is abnormal in about 70% of cases, with the most common abnormality being transient, patchy alveolar opacities. Pleural effusions are present in over 15% of cases, and eosinophils usually comprise more than 60% of pleural fluid cells.

Histopathology

The major histologic findings of CSS include eosinophil infiltration of vascular media and perivascular tissues accompanied by lymphocytes, plasma cells, and histiocytes. There is a necrotizing vasculitis of small arteries and veins and necrotizing extravascular granulomatosis.

Diagnosis

Using the American College of Rheumatology criteria,³¹ a sensitivity of 85% and a specificity of 99.7% are obtained if four or more of the following criteria are met: (1) asthma; (2) greater than 10% peripheral blood eosinophilia; (3) mononeuritis or polyneuropathy; (4) paranasal sinus abnormality; (5) transient alveolar opacities on chest radiograph; and (6) extravascular eosinophils on a vessel biopsy. The finding of a positive p-ANCA further strengthens the diagnosis.

Treatment and outcome

Glucocorticoids are the mainstay of therapy. Most patients respond favorably to prednisone administered at a dose of 0.5–1.5 mg/kg per day. Persistent ANCA positivity does not appear to correlate with underlying disease activity. Without treatment, CSS is characterized by a 50% mortality at 3 months. In contrast, with treatment a 5-year survival rate of 70% has been reported. Cardiac involvement, gastrointestinal disease, renal insufficiency, proteinuria, or central nervous system involvement are poor prognostic factors.

GOODPASTURE SYNDROME

Goodpasture syndrome is a rare disorder characterized by DAH and rapidly progressive glomerulonephritis, related to the production of autoantibodies reactive with glomerular and alveolar basement membranes. This syndrome is part of a spectrum of diseases known as anti-basement membrane antibody (ABMA) diseases (also referred to as anti-glomerular basement membrane (AGBM) diseases). In the majority of cases, lung and renal involvement occurs simultaneously (Goodpasture syndrome). However, in approximately one-third of cases, glomerulonephritis is the sole manifestation of disease and, in fewer than 5% of patients, DAH occurs without clinical evidence of renal involvement.

Clinical manifestations

The disease occurs two to three times more commonly in men than in women, with a peak incidence in the second and third decades of life. A genetic basis for ABMA production is suggested by its association in Caucasians with certain HLA alleles, including DRB1*1501 and DRB1*1502.³² Patients with Goodpasture syndrome who express these histocompatibility molecules experience severe renal disease with an associated poor prognosis.³²

Goodpasture syndrome commonly presents with cough, dyspnea, and hemoptysis. Fatigue, due to a combination of iron-deficiency anemia and

renal failure, may be the presenting symptom in patients without DAH. Gross hematuria and hypertension are uncommon, but microscopic hematuria, proteinuria, and red blood cell casts are common, as well as an increased serum creatinine. The chest radiograph shows patchy or diffuse alveolar infiltrates, and pulmonary physiology reveals increased diffusion capacity during periods of active bleeding (because of increased availability of hemoglobin to bind carbon monoxide).

The presence of serum or tissue ABMA in a patient with DAH and/or glomerulonephritis establishes the diagnosis of ABMA disease. These antibodies are almost always IgG, and most commonly of the subclass IgG₁. The level of the ABMA in the serum correlates with the severity of the renal disease but not with that of the lung disease.

Histopathology

The DAH in Goodpasture syndrome represents either bland pulmonary hemorrhage or pulmonary capillaritis. In those with capillaritis, alveolar wall necrosis is not seen. Similar to renal involvement in the systemic vasculitides (Chapters 58 and 67), the renal histology shows focal segmental necrotizing glomerulonephritis with crescent formation. Immunofluorescent staining of alveolar and glomerular basement membranes shows an uninterrupted linear deposition of immunoglobulin (Fig. 71.11).

Pathogenesis

The pathologic damage in Goodpasture syndrome is related to the binding of autoantibodies directed against the noncollagenous domain (α_3 -chain) of type IV collagen in the basement membrane.³³ Two dominant epitopes (E_A and E_B) have been identified in the α_3 -chain of type IV collagen. Despite the widespread distribution of type IV collagen in the body, disease expression is limited to the lungs and kidneys. This limited disease expression suggests the possibility that other factors allow exposure of this autoantigen selectively in alveolar or glomerular basement membranes. Since the epitopes in the α_3 -chain of type IV collagen are typically hidden, it is likely that some additional injury is necessary in order to reveal the hidden epitopes to the immune system.³³ For example, the clinical onset of alveolar hemorrhage has been associated with influenza A2 infection, hydrocarbon exposure, and cigarette smoking. On the other hand, the glomerular basement membrane is directly exposed to the vascular compartment through endothelial fenestrations, which probably explains the positive association between the level of ABMA and the severity of the glomerulonephritis.

Molecular mimicry has been linked to the pathogenesis of several autoimmune disorders, including multiple sclerosis and type I diabetes mellitus (Chapter 50). This concept proposes that a susceptible host is exposed to an infectious agent that has antigens that are immunologically similar to the host but sufficiently different to induce an immune response. Subsequently, tolerance to the autoantigen breaks down, and the pathogen-specific immune response is generated that cross-reacts with host structures, resulting in tissue damage. The possibility of molecular mimicry between basement membrane antigens and antigens from infectious agents is suggested by the finding of sequence homology between the α_3 -chain of type IV collagen in the basement membrane and a segment of influenza A hemagglutinin.³³

Autoreactive CD4 T cells are also required for the pathologic autoimmune response.³⁴ These autoreactive CD4 T cells require CD28 co-stimulation since blockade of CD28 reduces anti-basement membrane

Fig. 71.11 Immunofluorescence staining patterns of Goodpasture syndrome with immunoglobulin G deposits on the basement membrane. The characteristic linear deposit of antibody reacting with the continuously distributed basement membrane antigen(s) of (A) glomerular basement membrane (GBM) in the kidney and (B) alveolar basement membrane in the lung can be appreciated; this pattern easily distinguishes this condition from the more common granular or interrupted patterns of staining seen with immune complex forms of immune renal injury.

antibody production and prevents the development of experimental autoimmune glomerulonephritis.³⁵

Treatment and outcome

The establishment of a rapid diagnosis is essential since the severity of the renal lesion at the time of presentation correlates with the potential recovery of renal function. Prior to the introduction of plasmapheresis, the mortality of Goodpasture syndrome was between 75% and 90%. In patients with DAH alone, glucocorticoids are effective, but if glomerulonephritis is present (with or without alveolar hemorrhage) monotherapy is usually unsuccessful. Cytotoxic therapy, usually azathioprine or cyclophosphamide, may reverse the renal dysfunction, but the main role of these medications is to control alveolar hemorrhage. However, the combination of plasmapheresis, glucocorticoids, and cytotoxic therapy may be the most efficacious regimen, particularly for patients with oliguria who do not require hemodialysis. Plasmapheresis (3–6 l/day) is generally continued for 2 weeks.

The 2-year survival of patients with Goodpasture syndrome is approximately 50%, with the majority dying from alveolar hemorrhage, often precipitated by a concomitant infection. Severe renal failure reduces survival to 50% at 6 months. Renal biopsy provides both a diagnosis and prognostic information. Involvement of less than 30% of the glomeruli with crescent formation is associated with preserved renal function, significant response to therapy, and prolonged survival. However, when greater than 70% of the glomeruli are involved with crescent formation, progressive renal dysfunction is expected, requiring hemodialysis and consideration of renal transplantation.

LUNG INVOLVEMENT IN COLLAGEN VASCULAR DISEASES

CVD are a heterogeneous group of systemic autoimmune diseases, that frequently involve the lungs. The pleuropulmonary manifestations of these diseases are diverse, affecting all parts of the respiratory tract (i.e., airways, alveoli, blood vessels, and pleura) (Table 71.4). Although pulmonary complications generally occur in patients with well-established disease, occasionally the lung involvement is the first manifestation of the autoimmune disorder. This section discusses the pleuropulmonary manifestations of systemic lupus erythematosus (SLE), rheumatoid arthritis (RA), systemic sclerosis (SS), and polymyositis/dermatomyositis (PM/DM) (for a discussion of other manifestations in these diseases, see Chapters 51–56).

SYSTEMIC LUPUS ERYTHEMATOSUS

SLE is a disease of unknown etiology characterized by the presence of autoantibodies directed against various nuclear antigens. These autoantibodies and the resultant immune complexes mediate many of the manifestations of SLE (Chapter 51). This disease primarily affects young women (female-to-male ratio > 8:1) and may involve and derange the function of virtually every organ system. Pleuropulmonary involvement occurs at some point in the disease course in 38–89% of cases.³⁶ Thus, the respiratory system is affected more commonly in SLE than in any other CVD. That said, infectious pneumonia remains the commonest cause of pulmonary disease in this patient population, and infection is a common cause of death. Thus, in SLE patients presenting with a febrile illness and pulmonary infiltrates, a community-acquired or opportunistic infection must be promptly excluded.

Table 71.4 Pleuropulmonary manifestations of collagen vascular diseases

	SLE	RA	SS	PM/OM
Pulmonary hypertension	+	+	+++	±
Vasculitis	+	±	±	–
Pleural disease	+++	+++	+	–
Bronchiolitis obliterans	±	++	+	+
Aspiration pneumonia	–	–	++	++
Diaphragmatic dysfunction	++	–	–	±
Lung nodules	–	++	–	–
Diffuse alveolar damage	+	±	±	+
BOOP	±	+	±	+
UIP	+	++	+++	++
Capillaritis	++	+	±	±
LIP	+	+	+	±
NSIP	+	++	+	++

BOOP, bronchiolitis obliterans organizing pneumonia; LIP, lymphocytic interstitial pneumonitis; NSIP, nonspecific interstitial pneumonitis; PM/DM, polymyositis/dermatomyositis; RA, rheumatoid arthritis; SLE, systemic lupus erythematosus; SS, systemic sclerosis; UIP, usual interstitial pneumonitis.

Acute lupus pneumonitis

Acute lupus pneumonitis is an uncommon pulmonary manifestation of SLE, occurring in fewer than 5% of cases.³⁷ The clinical presentation mimics that of an infectious pneumonia with the abrupt onset of fever, cough, and dyspnea. Serum complement levels are often low and the chest radiograph typically shows diffuse alveolar opacities. It may be accompanied by pericarditis and often pleuritis and pleural effusion.

It can be difficult to distinguish acute lupus pneumonitis from an infectious pneumonia: BAL followed by thoracoscopic lung biopsy is often recommended prior to instituting corticosteroid therapy. The histopathology varies and includes diffuse alveolar damage, BOOP, NSIP, or a combination of these.

There are no controlled trials of therapy for acute lupus pneumonitis. Treatment includes high-dose glucocorticoids (1–2 mg/kg per day) with or without accompanying cytotoxic drugs, such as cyclophosphamide. Mortality rates as high as 50% have been reported. In those patients who fail to respond to treatment, respiratory failure is the usual cause of death.

Diffuse alveolar hemorrhage

DAH occurs in fewer than 5% of patients with SLE, and it represents the initial manifestation of disease in 11–20% of those cases.³⁸ However, most cases develop in individuals with well-established diagnoses of SLE, usually with pre-existing lupus nephritis.

The symptoms of DAH mimic those of infectious pneumonia and acute lupus pneumonitis.³⁹ Hemoptysis is present in 42–66% of patients at presentation. Therefore, the absence of hemoptysis does not exclude the diagnosis, particularly in the setting of a falling hematocrit, diffuse pulmonary infiltrates, and blood-stained BAL fluid. When it is possible to test diffusing capacity (often not possible due to respiratory failure), this will be elevated because of the increased availability of hemoglobin to bind carbon monoxide. DAH in SLE is most often due to pulmonary capillaritis, but it can also be caused by diffuse alveolar damage. Immunofluorescence studies show granular deposits of IgG and C3 along alveolar walls, interstitium, and capillary endothelial cells.

There are no controlled trials for the treatment of alveolar hemorrhage in SLE. Glucocorticoids, cytotoxic drugs, and plasmapheresis have all been used in various combinations. The mortality rate associated with DAH is approximately 50%. Poor prognostic factors include the need for mechanical ventilation, presence of infection, and prior treatment with cyclophosphamide.

Lupus pleuritis

The pleura is the most common site of respiratory involvement in SLE, with pleurisy and pleural effusions occurring in 50–80% of patients. Lupus pleuritis may be the presenting manifestation of disease, but, more commonly develops in patients with established SLE. It is often recurrent. The clinical manifestations include chest pain, fever, and dyspnea, and the chest radiograph typically shows bilateral pleural effusions. The pleural fluid is serous or serosanguineous and exudative in nature. Compared to effusions in RA, the glucose is higher and the lactate dehydrogenase level is lower. The most helpful measurement is a pleural fluid antinuclear antibody titer greater than 1:160. Examination of the pleura reveals infiltration with plasma cells and lymphocytes accompanied by pleural thickening and fibrosis. Treatment with nonsteroidal anti-inflammatory drugs and/or glucocorticoids is usually effective for relief of pleural discomfort.

Interstitial lung disease

The presence of ILD in SLE was once thought to be uncommon, especially when compared to SS or RA.³⁷ However, minor interstitial abnormalities can be found on HRCT in approximately one-third of SLE patients who have a normal chest radiograph and physiological testing. The significance and natural history of these subclinical findings are uncertain. The presence of anti-SSA (Ro) has been noted in approximately 80% of lupus patients with interstitial changes. In addition, the prevalence of ILD is increased in a subset of SLE patients with scleroderma skin changes.

The diagnosis of SLE is usually well established in the subgroup of patients who develop the insidious form of ILD. The disease course is characterized by progressive dyspnea and cough; the chest radiograph shows reduced lung volumes and reticular interstitial infiltrates. A restrictive lung function pattern with reduced diffusing capacity and exercise-induced hypoxemia are typical. The histopathology of chronic interstitial disease in SLE resembles UIP, although cases of BOOP, lymphocytic interstitial pneumonitis (LIP), and NSIP have been described. Response to therapy depends on the underlying histopathology, with the UIP-like form being least responsive (see above).

Pulmonary vascular disease

In acutely ill SLE patients, a syndrome of acute reversible hypoxemia has been described. These patients have hypoxemia and a widened alveolar-arterial oxygen gradient with a normal chest radiograph and ventilation-perfusion scan. The etiology of this syndrome is unknown, but complement-mediated intravascular neutrophil aggregation has been suggested. The hypoxemia usually resolves with glucocorticoid treatment.

Although previously thought to be unusual, the development of pulmonary hypertension secondary to plexogenic arteriopathy has been increasingly noted in SLE, with an incidence ranging from 5% to 14%. Pulmonary hypertension in SLE has been associated with the presence of Raynaud syndrome, serositis, digital vasculitis, and antiphospholipid antibodies.⁴⁰ Dyspnea and fatigue, despite a normal chest radiograph, is the most common presentation. As the pulmonary hypertension advances, the central pulmonary arteries enlarge. Pulmonary function testing shows an isolated decrease in the diffusing capacity for carbon monoxide. Ventilation-perfusion scanning and pulmonary angiography may be indicated in order to exclude thromboembolic disease. Treatment consists of oxygen and calcium-channel blockers. It remains unknown whether the use of continuous intravenous epoprostenol can alter exercise capacity and cardiopulmonary hemodynamics in patients with secondary pulmonary hypertension due to SLE.

Respiratory muscle dysfunction

The *shrinking or vanishing-lung syndrome* is due to diaphragmatic weakness as well as weakness of other respiratory muscles.⁴¹ This entity accounts for the findings of dyspnea without evidence of interstitial infiltrates or pulmonary vascular disease. It is estimated to occur in 25% of patients with SLE. The chest radiograph typically shows elevated diaphragms and basilar atelectasis. The pathogenesis of respiratory muscle weakness is unknown, but it is not associated with generalized muscle weakness. Glucocorticoids are frequently ineffective in the treatment of this syndrome. Improvement has been noted with inhaled β -agonist and theophylline therapy. Despite a variable response to therapy, it is unusual for this manifestation of SLE to be progressive.

RHEUMATOID ARTHRITIS

RA is characterized by the presence of a symmetric, inflammatory polyarthritis occurring more frequently in women, with a 2:1 female-to-male ratio (Chapter 52). Disease onset is most commonly in the fourth to fifth decades of life. The pleuropulmonary complications of RA occur more commonly in individuals with subcutaneous nodules, high titers of rheumatoid factor, and more severe chronic articular involvement. Although RA itself is more common in women, the pleuropulmonary manifestations have a higher incidence in men. The pleuropulmonary complications of RA are numerous, but it is important to remember that treatment-related lung toxicity and pulmonary infections are sometimes difficult to differentiate from the primary pleuropulmonary manifestations of the disease.

Pleuritis and pleural effusions

As in SLE, pleural abnormalities are one of the most common pulmonary complications of RA.⁴² Pleural effusions are clinically evident in approximately 5% of patients, and these may occur prior to the development

CLINICAL PEARLS

LUNG INVOLVEMENT IN RHEUMATOID ARTHRITIS (RA)

- >> RA is more common in women, but pleuropulmonary complications occur more frequently in men
- >> Factors associated with pleuropulmonary complications of RA include more severe articular involvement, subcutaneous nodules, and high levels of rheumatoid factor
- >> Pleural effusions are the most common complication, characterized by an exudate and a low glucose and low pH
- >> The differentiation of rheumatoid nodules from malignant lesions can be difficult
- >> The rapid growth of a nodule should prompt aggressive investigation for a malignant cause

of arthritis. Pleural disease is often discovered as an incidental finding on routine chest radiographs, but nonspecific chest pain, dyspnea, and fever are not unusual. The effusion may be unilateral or bilateral and may coexist with interstitial lung disease.

Typically, the effusion is an exudate, with a glucose level less than 30 mg/ml in 70–80% of cases. The mechanism underlying the low pleural fluid glucose is impaired membrane transport of glucose. A low pleural fluid pH is thought to occur secondary to impaired carbon dioxide exit from the pleural space. If the effusion is chronic, the cholesterol concentration can be increased, and the pleural fluid may have a milky appearance (pseudochylothorax). Cytologic examination typically reveals multinucleated giant cells, spindle-shaped macrophages, and necrotic debris.

Most rheumatoid effusions are small and asymptomatic, and therefore require no treatment. They resolve over several months without complications. Occasionally, fibrothorax can occur. The use of glucocorticoids for active articular disease hastens the resolution of the pleural process.

Rheumatoid nodules

Rheumatoid or necrobiotic nodules are the only pleuropulmonary manifestation specific for RA. These nodules are most commonly seen in men with active articular disease, high rheumatoid factor titers, and subcutaneous nodules. Most individuals are asymptomatic and are diagnosed on routine chest radiograph. Radiographically, these nodules may be singular or multiple with an upper to mid-lung zone predominance. Cavitation occurs in approximately 50% of cases. HRCT of the lung indicates a higher frequency of nodules than previously thought. Rarely, subpleural necrobiotic nodules can erode into the pleural space, resulting in a pneumothorax with a complicating bronchopleural fistula. It can be difficult to differentiate these nodules from malignant lesions, and frequently open-lung biopsy is necessary. Evidence on chest radiograph of rapid growth should prompt an aggressive diagnostic evaluation. Usually, no treatment is necessary.

Caplan syndrome refers to the rapid development of pulmonary nodules with an upper-lung-zone predominance, originally described in Welsh coalminers with RA. Histologically, these nodules are identical to necrobiotic nodules. Other occupational dust exposures have also been associated with this syndrome.

Pulmonary vascular disease

Although systemic vasculitis with nailfold infarcts, cutaneous ulcers, mononeuritis multiplex, and digital ischemia can develop in RA, pulmonary vascular disease is the least common pleuropulmonary complication of RA. Rarely, pulmonary capillaritis can result in DAH.⁴³ In contrast to SLE and SS, primary pulmonary vascular disease resulting in pulmonary hypertension is rare.

Airway disease

Airflow limitation is a common finding in patients with RA, being present in approximately one-third of patients. The mechanism(s) responsible for airway disease is poorly understood. The interplay of cigarette smoking and RA may play a role.

A life-threatening complication of RA is upper-airway obstruction, resulting from synovitis of the cricoarytenoid joint. Common presenting complaints include a sore throat, hoarseness, and fullness in the throat. It can progress to inspiratory stridor and upper-airway obstruction. This complication occurs more commonly in women, particularly in those with advanced RA. Seventy-five percent of patients were found to have cricoarytenoid abnormalities when screening with direct or indirect laryngoscopy and computed tomography was utilized. The treatment of cricoarytenoid arthritis includes anti-inflammatory medications.

Bronchiolitis obliterans is a progressive form of obstructive lung disease that is being increasingly recognized as a complication of RA.⁴⁴ This entity was thought to develop secondary to the use of penicillamine for the treatment of RA, but most cases occur in the absence of this therapy. The histopathologic lesion of bronchiolitis obliterans is constrictive bronchiolitis, which is characterized by concentric submucosal and peribronchiolar fibrosis resulting in extrinsic compression and obliteration of the bronchiolar lumen. The typical clinical presentation is with insidious onset of cough and dyspnea, with a normal or hyperinflated chest radiograph. This complication occurs more commonly in women than in men. Pulmonary function studies show airflow limitation with hyperinflation and a reduced diffusing capacity. Expiratory HRCT shows multiple areas of air trapping (mosaic pattern). Some individuals respond to high-dose glucocorticoids and cytotoxic drugs, but most patients with bronchiolitis obliterans progress to respiratory failure.

Bronchiectasis occurs at an increased frequency in RA, usually in individuals with long-standing articular disease. Productive cough and dyspnea are the most common respiratory symptoms. In most patients, bronchiectasis is not clinically significant. Recurrent pneumonia and respiratory failure are potentially fatal complications of this problem.

Interstitial lung disease

Although ILD is a common complication of RA, the incidence is difficult to determine, since different methods of detection have been employed and dissimilar populations of patients have been studied. However, clinically significant ILD occurs in approximately 14% of patients.⁴⁵ The development of ILD in relation to the onset of arthritis is variable. Most often, the ILD develops subsequent to arthritis, but, in approximately 20% of patients, the lung disease precedes the onset of arthritis.

The most common histopathologies identified in this patient population are UIP, LIP, NSIP, and BOOP (see above). The clinical manifestations of ILD in RA resemble those seen in idiopathic disease and

include a dry, nonproductive cough and dyspnea on exertion. The chest radiograph and HRCT show increased reticular markings with a predilection for the periphery and lower-lung zones. Often, pleural abnormalities accompany the interstitial changes. With advanced disease, progression to honeycomb lung occurs. LIP usually occurs in cases of RA complicated by Sjögren syndrome: the presence of keratoconjunctivitis sicca and xerostomia in a patient with RA and ILD should suggest this histologic type.

In general, ILD in RA appears more indolent than in idiopathic interstitial pneumonitis. Thus, due to uncertain treatment benefits and possible adverse effects, the decision to institute therapy should be based on clinical, radiographic, and physiologic deterioration.

Drug-induced lung disease

Methotrexate and gold are the two main anti-RA drugs capable of causing lung injury. Methotrexate administered weekly (10–20 mg/week) is associated with the development of interstitial changes in 1–5% of patients with RA.⁴⁶ No correlation with age, sex, disease duration, or cumulative dose has been identified. The clinical presentation is subacute in nature, with fever, cough, and dyspnea occurring 1–5 months after the initiation of the drug. The chest radiograph shows mixed interstitial–alveolar infiltrates. Nonspecific laboratory abnormalities include leukocytosis, sometimes with mild eosinophilia, and an elevated erythrocyte sedimentation rate. In most cases, BAL reveals a lymphocytosis. Histologically, cellular NSIP is seen with areas of organizing pneumonia. Noncaseating, granulomatous inflammation similar to that seen in hypersensitivity pneumonitis may also be present. The primary treatment of methotrexate-induced pneumonitis is withdrawal of methotrexate, plus appropriate supportive care.

Gold-induced pneumonitis occurs in fewer than 1% of RA patients treated with gold. Dyspnea and cough usually begin after 4–6 weeks of therapy; eosinophilia occurs in a minority of patients. The chest radiograph typically reveals mixed alveolar–interstitial opacities with an upper-lung zone predilection. The histology is similar to that seen in RA patients with ILD. Thus, the differentiation of gold-induced pneumonitis from RA-associated interstitial lung disease can only be established when discontinuation of the medication results in remission.

SYSTEMIC SCLEROSIS (SCLERODERMA)

SS is characterized by excessive deposition of extracellular matrix in the skin and internal organs, and vascular involvement (Chapter 55). The degree of visceral organ involvement determines morbidity and mortality. Pulmonary involvement occurs in 70–100% of patients with SS. There is no correlation with the degree of extrapulmonary disease. Interstitial lung disease is the most common pulmonary manifestation of SS. Of note, with the improved mortality associated with renal involvement in SS, lung disease has become the most important cause of morbidity and mortality.⁴⁷

Interstitial lung disease

The incidence of ILD in SS depends on the method of detection. Autopsy studies have reported an ILD incidence of 60–100% of cases, whereas studies based on chest radiographs have noted interstitial changes in only 14–66% of cases.

Similar to other ILD, cough and dyspnea on exertion are the most common symptoms. Physical examination reveals bibasal rales. Clubbing is unusual, due perhaps to capillary destruction in the nail beds. Radiographic findings include basal reticulonodular infiltrates, enlargement of pulmonary arteries, and progressive volume loss with associated honeycomb change. Pulmonary function testing reveals restrictive lung disease, preservation of flow rates, and decreased diffusing capacity. A disproportionate decrease in diffusing capacity compared to lung volume changes should suggest pulmonary hypertension, especially in individuals with limited scleroderma (calcinosis, Raynaud's phenomenon, esophageal dysmotility, sclerodactyly, telangiectasia [CREST] syndrome). The predominant histopathologic abnormality is UIP with honeycomb changes and is identical to that seen in IPF. Rarely, LIP may complicate cases of SS associated with Sjögren syndrome. Although the 5-year survival for SS patients with ILD is 38–45%, it is better than that of patients with IPF.⁴⁸

Pulmonary vascular disease

Pulmonary hypertension is a frequent complication of SS, occurring in approximately 30% of patients with diffuse scleroderma and in 10–50% of those with limited scleroderma (Chapter 55). The pulmonary hypertension may either be associated with interstitial fibrosis or result from involvement of small and medium-sized arteries and arterioles with smooth-muscle hyperplasia, medial hypertrophy, and intimal proliferation (plexogenic). Direct involvement of the pulmonary circulation is more common with limited scleroderma while pulmonary hypertension in patients with diffuse scleroderma is more likely associated with ILD.

The clinical presentation is characterized by the insidious onset of fatigue and dyspnea on exertion. Physical examination and chest radiographs show signs typical of pulmonary hypertension, while decreased diffusing capacity is seen on pulmonary function testing.

The prognosis of isolated pulmonary hypertension, with a 2-year survival rate of 40%, is worse than that for pulmonary hypertension associated with interstitial fibrosis.⁴⁹ A recent study using continuous intravenous epoprostenol in patients with hypertension associated with scleroderma showed improvement in exercise capacity and cardiopulmonary hemodynamics as compared to control subjects treated with conventional therapy alone.⁵⁰

Pleural disease

Clinically significant pleural disease is uncommon in SS, although pleural fibrosis and adhesions are frequent findings in postmortem studies.

Aspiration pneumonia

Patients with SS have an increased incidence of esophageal dilatation and decreased peristalsis: this esophageal dysmotility predisposes to aspiration pneumonia. However, it is unclear if there is any relationship between gastroesophageal reflux and the development of lung disease. One study showed that gastroesophageal reflux did not correlate with physiologic impairment of the lung in these patients.⁵¹

POLYMYOSITIS/DERMATOMYOSITIS

Polymyositis and dermatomyositis are idiopathic inflammatory myopathies characterized by proximal muscle weakness and, in the case of DM, a characteristic skin rash (Chapter 56). Pulmonary complications in

PM/DM are important causes of morbidity and mortality and may overshadow the muscle involvement. Approximately 40% of patients with PM/DM have pulmonary involvement. As compared to the other collagen vascular diseases, lung involvement in PM/DM does not primarily affect the airways or the pleura.

Aspiration pneumonia

Aspiration pneumonia is the most common pulmonary complication in patients with PM/DM. Upper-airway protection is impaired, secondary to a reduced cough reflex resulting from weakness of striated muscles of the soft palate, pharynx, and upper esophagus. This weakness results in dysphagia, and, as a consequence, aspiration pneumonia occurs in 15–20% of PM/DM patients. A history of aspiration pneumonia carries a poor prognosis since it tends to occur in patients with more extensive muscle involvement.

Respiratory muscle dysfunction

Hypercapnic respiratory failure secondary to generalized respiratory muscle dysfunction occurs infrequently in patients with PM/DM. Mucus plugging with resultant atelectasis occurs secondary to the inadequate cough reflex. Chest radiograph may reveal reduced lung volumes with associated bibasal atelectasis. The respiratory muscle weakness results in both inspiratory and expiratory dysfunction, and measurement of maximal inspiratory and expiratory pressures is useful in the determination of respiratory muscle dysfunction as the cause of restrictive lung disease in patients with PM/DM. Sequential measurements are useful to monitor the clinical course and response to therapy.

Interstitial lung disease

Depending on the method of screening, 5–30% of patients with PM/DM have interstitial lung disease.⁴⁸ UIP is the commonest histopathologic lesion, but NSIP, DAH secondary to capillaritis, diffuse alveolar damage, and BOOP may also occur. There is no relationship between the interstitial changes and the degree of skin and/or muscle involvement.

Depending on the underlying lung pathology, several clinical syndromes may occur. The most common presentation is insidious onset of cough and dyspnea due to UIP or NSIP. Laboratory findings include elevated creatine phosphokinase and anti-Jo-1 antibodies, which are directed against histidyl-tRNA-synthetase. This autoantibody specificity serves as a marker for the subset of PM/DM patients who have interstitial fibrosis, being present in 50% of these individuals (Chapter 56). The chest X-ray appearance of ILD in PM/DM is similar to that seen in IPF. Physiologic testing shows a restrictive pattern with reduced diffusing capacity. The natural history and optimal treatment of interstitial lung disease in PM/DM are unknown.

Some PM/DM patients present with acute onset of diffuse alveolar infiltrates and associated respiratory failure. The underlying histopathologic lesion may be diffuse alveolar damage, capillaritis, or BOOP. The differentiation of diffuse alveolar damage from capillaritis and BOOP is critical since the response to treatment and survival are dramatically different. In diffuse alveolar damage, recovery is unusual despite aggressive anti-inflammatory and immunosuppressive treatment. On the other hand, both BOOP and capillaritis are responsive to standard therapeutic options.

Sarcoidosis

David R. Moller

72

Sarcoidosis is a multisystem disorder of unknown etiology characterized by noncaseating epithelioid granulomas in affected organs.^{1–3} The disease most commonly affects the lungs and intrathoracic lymph nodes, although granulomatous inflammation may be present in any organ system. The clinical manifestations and course of sarcoidosis vary greatly.⁴ An estimated 30–60% of patients with sarcoidosis are asymptomatic, usually with isolated bilateral hilar adenopathy. Symptomatic manifestations most frequently involve the respiratory system, with symptoms of cough, dyspnea, and chest discomfort. Löfgren syndrome is a form of acute sarcoidosis characterized by erythema nodosum, bilateral hilar adenopathy, polyarthritis, and often uveitis. Other clinical manifestations depend on the range and extent of extrapulmonary involvement (Table 72.1).

■ EPIDEMIOLOGY ■

Sarcoidosis is found worldwide, though there are striking differences in the prevalence of the disease in different geographic areas and racial groups.⁵ In Europe and North America the prevalence is estimated to range from 10 to 64 cases per 100 000, with higher rates in African-American populations. In countries where tuberculosis is common and health care uncertain, no reliable epidemiologic data are available because of the difficulty in distinguishing between sarcoidosis and tuberculosis. Worldwide there is a slight female preponderance. Although all ages can be affected, more than 80% of cases are diagnosed between the ages of 20 and 50 years.

The frequency of different clinical manifestations and disease severity varies among different groups.^{4,5} Löfgren syndrome has a particularly high frequency in Scandinavian countries and Ireland, but occurs in fewer than 5% of African-American patients with sarcoidosis. Lupus pernio, a disfiguring nodular facial condition associated with chronic sarcoidosis, is more frequent in patients of African descent. Cardiac sarcoidosis affects up to 50% of Japanese patients with sarcoidosis, but fewer than 10–25% of European and North American patients. In a study of mortality data from hospitals in the USA from 1979 to 1991, age-adjusted mortality was consistently higher among blacks than whites, and among women compared with men. Retrospective studies

suggest that sarcoidosis is the direct cause of death in <1–6% of cases, usually from pulmonary, cardiac, or neurologic involvement.

■ GENETICS ■

There is substantial evidence for a genetic predisposition to sarcoidosis. This was initially suggested from the familial clustering that occurs in approximately 5–16% of patients. A recent US-based multicenter study of sarcoidosis called ACCESS compared 706 newly diagnosed, biopsy-proven sarcoidosis cases to age-, sex-, and race-matched controls.⁶ This

■ KEY CONCEPTS ■

- >> Sarcoidosis is characterized by noncaseating epithelioid granulomas and mononuclear cell inflammation, usually in multiple organ systems
- >> Genetic susceptibility to sarcoidosis and its various clinical presentations is suggested by family studies and associations with major histocompatibility complex (MHC) haplotypes
- >> Granulomatous inflammation in sarcoidosis is characterized by oligoclonal expansions of Th1 cells and activated mononuclear phagocytes producing tumor necrosis factor (TNF)- α , interleukin-12 (IL-12), and IL-18
- >> Pulmonary involvement with bilateral hilar adenopathy, restrictive or obstructive interstitial lung occurs in over 90% of patients
- >> Symptomatic, extrapulmonary sarcoidosis is often chronic, requiring treatment to prevent serious permanent organ damage
- >> Standard treatment for progressive, symptomatic sarcoidosis involves corticosteroid therapy, although the long-term benefits remain unproven

Table 72.1 Major clinical features of systemic sarcoidosis

Organ system (approx. % involvement)	Major clinical features
Pulmonary (90)	Bilateral hilar adenopathy, restrictive and obstructive disease, fibrocystic disease, bronchiectasis, mycetomas
Upper airway (5–10)	Hoarseness, laryngeal or tracheal obstruction, nasal congestion, sinusitis, saddle-nose deformity
Ocular (25)	Anterior and posterior uveitis, chorioretinitis, conjunctivitis, optic neuritis, glaucoma, lacrimal gland enlargement
Skin (20)	Erythema nodosum, chronic nodules and plaques, lupus pernio, alopecia
Hepatic (10)	Hepatomegaly, pruritus, jaundice, cirrhosis
Cardiac (5–10)	Arrhythmias, heart block, cardiomyopathy, sudden death
Central nervous system (5–10)	Cranial neuropathy, e.g., Bell's palsy, aseptic meningitis, brain mass, seizures, obstructing hydrocephalus, myelopathy, polyneuropathy, mononeuritis multiplex
Salivary and parotid gland (10)	Salivary and parotid gland enlargement, sicca syndrome
Hematologic (30–50)	Lymphadenopathy, splenomegaly, hypersplenism, anemia, lymphopenia, thrombocytopenia
Joints/musculoskeletal (10–20%)	Polyarthritis, bone cysts, Achilles tendinitis, heel pain, myopathy
Endocrine (< 10)	Hypercalciuria (more common), hypercalcemia, hypopituitarism, diabetes insipidus
Renal (< 5)	Renal calculi, nephrocalcinosis, renal failure, epididymitis, testicular mass

study found a higher relative risk in siblings of sarcoidosis cases (odds ratio (OR) ~ 5.8) than in parents (OR ~ 3.8). Both the ACCESS study and a UK study found higher adjusted familial relative risk estimates for Caucasians than blacks, suggesting that genetic factors have a greater influence in susceptibility to sarcoidosis in Caucasians.

Genetic association studies support a consensus view that major histocompatibility complex (MHC) class II alleles are the major contributor to disease susceptibility across different ethnic populations in sarcoidosis. Human leukocyte antigen (HLA)-DR3 is associated with increased sarcoidosis risk in Scandinavian and European populations whereas HLA-DR1 and -DR4 alleles are associated with disease protection. The ACCESS study found a significant association between HLA-DRB1*1101 in both African-Americans and Caucasians, whereas HLA-DRB1*1501 was associated with sarcoidosis risk only in Caucasians.⁷

HLA class II alleles have also been associated with clinical course. DR3 haplotypes and specifically HLA DRB1*0301 or the closely linked DQB1*0201 alleles are associated with favorable outcomes (Löfgren syndrome, acute arthritis, stage I chest radiograph, or remission within 2 years) whereas DR14 and DR15 are associated with severe, chronic disease, in European and Japanese populations.⁸ The ACCESS study found DRB1*1501 or the closely linked DQB1*0602 alleles were associated with more severe or chronic disease.

Studies of non-HLA polymorphisms have yielded few clues to the genetic basis of sarcoidosis. Polymorphisms of the angiotensin-converting enzyme (ACE) gene have been associated with sarcoidosis risk in Japan, but not elsewhere. In one study, specific tumor necrosis factor- α (TNF- α) gene polymorphisms were associated with patients with Löfgren syndrome, although the overall disease frequency of the

sarcoidosis cohort did not differ from that of a control group. Two studies report associations with sarcoidosis and the CC chemokine receptors CCR2 and CCR5.

Family linkage studies confirm the importance of genes from the MHC locus in determining susceptibility to sarcoidosis. A German study employing genome-wide microsatellite analysis found strongest linkage to the MHC class II locus on chromosome 6p with minor linkage peaks on chromosomes 1, 3, 9, and X.⁹ A US-based study of African-Americans called SAGA found the highest linkage peak on chromosome 5q and minor peaks on chromosome 1, 2, 9, 11, and 20.¹⁰ No significant linkage to the MHC region on chromosome 6 was found in the SAGA study, possibly due to the influence of Caucasian gene admixture among African-Americans in the USA. Recently, German and US investigators report that the butyrophilin-like 2 (BTNL2) gene within the MHC locus is associated with sarcoidosis risk in Caucasians and, to a lesser extent, African-American populations.¹¹ BTNL2 is a member of the B7 receptor family that functions in T-cell costimulation, leading to the hypothesis that this gene plays a role in the polarized Th1 granulomatous response in sarcoidosis.

ENVIRONMENTAL FACTORS

Environmental factors have been implicated in the etiology of sarcoidosis with reports of time-space clustering and a higher incidence of disease in spring months. Health care workers, military personnel and firefighters may have a higher incidence of sarcoidosis.

The largest reported study of sarcoidosis etiology (ACCESS) failed to detect any environmental or occupational risk factor that carried an

OR > 2.0 and an exposure prevalence of > 5% (pre-study goal).¹² Weak positive associations (OR ~ 1.5) were found for insecticide use at work, mold/mildew exposures at work, and musty odors, suggesting possible links to microbial-rich environments. Sarcoidosis was not found to be associated with exposure to heavy metals, including beryllium, wood dusts, or rural residence. The ACCESS study found a robust negative association of smoking and sarcoidosis risk, confirming earlier studies. The lack of a single dominant exposure associated with sarcoidosis risk is consistent with the concept that gene-environment interactions are important in causing disease.

Since the initial descriptions of sarcoidosis, investigators have postulated an infectious cause of the disease based on its clinical similarities to other infectious diseases, most notably tuberculosis. Reports of acid-fast organisms and cultivatable mycobacterial or cell wall-deficient organisms have not been confirmed in other centers. Studies using polymerase chain reaction (PCR) methods find mycobacterial DNA or RNA in 0–80% of tissues from patients with sarcoidosis; the variability of results from different centers precludes a consensus on a role for mycobacterial organisms in sarcoidosis.¹³ Japanese investigators report the presence of *Propionibacterium acnes* or *granulosum* genomes in 80–98% of sarcoidosis tissues from Japan and Europe but also in 0–60% of control tissues.¹⁴ Given that these organisms are part of the normal skin and upper-airway flora, a pathogenic role for these organisms remains uncertain. The presence of high titers of antibodies against many viral agents (Epstein-Barr virus, human herpes virus-8, cytomegalovirus, parainfluenzae, adenovirus) and bacterial antigens (*Chlamydia* spp., *Borrelia burgdorferi*) in sarcoidosis sera are thought to reflect generalized B-cell activation and not a direct causal relationship. An infectious etiology of sarcoidosis is supported by observations of apparent transmissibility of systemic granulomas by allogeneic bone marrow or cardiac transplantation derived from individuals with sarcoidosis.

One clue to sarcoidosis etiology is the observation made in the 1940s by A. Kveim that the intradermal inoculation of a suspension of

sarcoidosis tissue results in a nodular skin reaction with sarcoid-like granulomas in patients with suspected sarcoidosis. In this reaction, well-formed granulomas take 2–4 weeks to develop. The active component appears to be a poorly soluble microparticulate with relative resistance to neutral detergents, nucleases, proteases, heat, and acidity.¹⁵

A recent study used a limited proteomic approach to identify potential pathogenic antigens in sarcoidosis tissues based on the biochemical properties of the Kveim reagent and not on *a priori* hypotheses regarding specific infectious or autoimmune causes. This approach detected the mycobacterial catalase-peroxidase protein (mKatG) in over 50% of sarcoidosis tissues.¹⁶ Immunoglobulin G (IgG) responses to mKatG were detected in ~50% of sarcoidosis patients, supporting the premise that mKatG is a pathogenic antigen and that mycobacterial organisms trigger a subset of sarcoidosis.

Although direct demonstration of an infectious etiology remains unproven, many investigators favor the hypothesis that certain classes of microbial organisms trigger sarcoidosis in those with genetic susceptibility. Whether autoimmunity plays a role in sarcoidosis is unknown, since there are no disease-specific autoantibodies.

IMMUNOLOGY/PATHOGENESIS

The histologic hallmark of sarcoidosis is the presence of discrete, compact noncaseating granulomas (Fig. 72.1). The dominant cell in the central core is the epithelioid cell, thought to be a differentiated form of mononuclear phagocyte. CD4 lymphocytes and mature macrophages are interspersed throughout the epithelioid core, whereas both CD4 and CD8 lymphocytes are seen around the periphery of the granuloma. Multinucleated giant cells, often containing cytoplasmic inclusions such as Schaumann bodies or asteroid bodies, are scattered throughout the inflammatory locus. In the lung, granulomas tend to form along areas that are rich in lymphatic vessels, such as bronchovascular, bronchial

Fig. 72.1 (A) Open-lung biopsy showing typical noncaseating epithelioid granuloma, giant cells, and lymphocytic infiltrates in lung parenchyma in sarcoidosis. (B) Lymph node biopsy showing extensive replacement with well-defined epithelioid granulomas in a patient with sarcoidosis.

submucosal, subpleural, and interlobular septal regions, as well as alveolar and bronchial walls. Granulomas in sarcoidosis tend to vary from cellular forms to acellular, hyalinized ghosts of granulomas that probably reflect an evolution to an inactive or fibrotic form.

The concept of sarcoidosis as a disorder of enhanced cell-mediated immune processes at sites of granulomatous inflammation was based on landmark studies in the 1980s using bronchoalveolar lavage (BAL). These studies demonstrated increased proportions and numbers of activated CD4 BAL lymphocytes in pulmonary sarcoidosis. Prior to these findings, sarcoidosis had been thought of as a disease of immune depression exemplified by circulating lymphopenia and cutaneous anergy. In sarcoidosis, most BAL T cells are CD4 with a CD45RO "memory" phenotype expressing high levels of activation molecules DR and very late activation antigen-1 (VLA-1, CD49a) and reduced surface density of the CD3:T-cell receptor (TCR) complex.

Direct evidence that sarcoidosis is an antigen-driven disorder is provided by studies analyzing TCR gene expression. These studies document the expansion of oligoclonal populations of lung (BAL), blood or skin (Kveim biopsy) T cells expressing specific V α or V β TCR genes. The most compelling data derive from DR17(3)/DQ2 Swedish patients who have greatly expanded numbers of V α 2.3(AV2S3) T cells in the lung.¹⁷ Sequence analyses demonstrate that expanded oligoclonal $\alpha\beta$ T-cell subsets in sarcoidosis often contain shared amino acid motifs in the CDR3 region of their V β or V α /J α genes, consistent with a conventional antigen-driven T-cell response. Despite intense efforts, the specificities of these expanded T-cell clones have yet to be identified.

As many as 30% of sarcoidosis patients have greater proportions of $\gamma\delta$ + T cells in their blood, predominantly of the V γ ₉V δ ₂ subset. As $\gamma\delta$ + T cells are rarely found around granulomas in lymph nodes or skin, their role in the pathogenesis of sarcoidosis remains uncertain.

Alveolar macrophages are thought to play a central role in the development of granulomatous inflammation in sarcoidosis by presenting disease-specific antigens and producing cytokines that regulate granuloma formation.¹⁸ Alveolar macrophages from patients with sarcoidosis express higher levels of surface class II MHC molecules, leukocyte function associated-antigen-1 (LFA-1), intracellular adhesion molecule-1 (ICAM-1), and the accessory molecules CD86 (B7.2), CD80 (B7.1), and CD40 than do alveolar macrophages from healthy controls. These characteristics probably contribute to the enhanced ability of sarcoidosis alveolar macrophages to present antigen to autologous T cells compared to normal alveolar macrophages. Importantly, sarcoidosis alveolar macrophages spontaneously produce the proinflammatory cytokines TNF- α , interleukin (IL)-6, IL-1 α , and IL15. These lung cells also produce increased amounts of lysozyme, ACE, reactive oxygen species, fibronectin, and insulin-like growth factor-1 (IGF-1) and lower than normal amounts of the counterinflammatory prostaglandin E₂.

Several chemotactic cytokines (chemokines) are expressed by BAL cells in sarcoidosis, including monocyte chemoattractant protein (MCP)-1, RANTES, macrophage inflammatory protein (MIP)-1, monokine-induced by interferon (IFN)- γ (MIG), IL-8, and osteopontin (early T-lymphocyte activation protein). These chemokines probably assist in the recruitment of T cells, blood monocytes, and granulocytes to inflammatory loci in sarcoidosis. Natural killer (NK) cells, B cells, and mast cells are also occasionally seen around granulomas; their contributions to the inflammatory response are uncertain.

The granulomatous inflammation in sarcoidosis is dominated by a polarized Th1 cytokine profile at time of diagnosis (Fig. 72.2).¹⁸ BAL

studies demonstrate increased mRNA and protein levels of IFN- γ and IL-2, with low or undetectable levels of IL-4 and IL-5 in pulmonary sarcoidosis. Consistent with a polarized Th1 process, IL-12 and IL18 are upregulated in BAL fluid and in cells from the lungs and lymph nodes of patients with sarcoidosis,¹⁹ while most sarcoidosis BAL T cells express a functional, high-affinity IL-12 receptor with β_2 -chains and the chemokine receptors CXCR3 and CCR5. It is not known whether this Th1

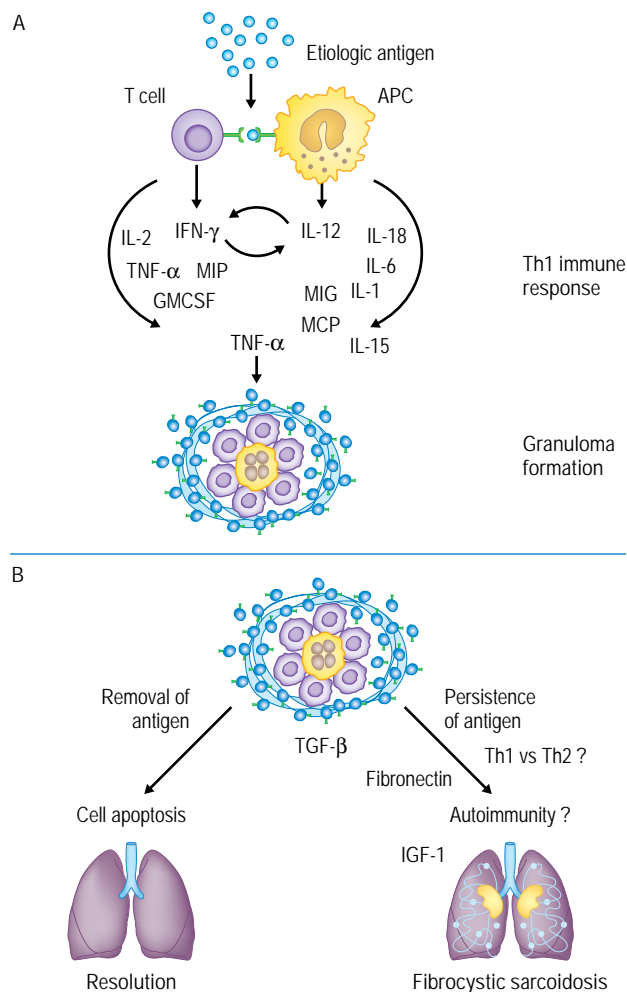

Fig. 72.2 Hypothetical model of the immunopathogenesis of sarcoidosis. **(A)** Granuloma formation in sarcoidosis results from stimulation by an insoluble antigen that evokes an adaptive T-cell immune response and stimulates the production of tumor necrosis factor (TNF) and interleukin-12 (IL-12) along with other cytokines from mononuclear phagocytes and dendritic cells. **(B)** Remission versus chronic fibrotic sarcoidosis. After the removal of stimulating antigen(s), suppression of Th1-driven granuloma formation is mediated in part by transforming growth factor- β (TGF- β), followed by granuloma resorption with cell apoptosis. Progressive fibrosis results from persistent, possibly autoimmune, antigenic stimulation in the presence of either Th1 or Th2 cytokines and TGF- β , insulin-like growth factor-1 (IGF-1), and other profibrotic mediators.

polarization persists in chronic, fibrotic sarcoidosis or there is a transition to a more profibrotic Th2 cytokine profile. Recent reports of increased IL-13 expression in some sarcoidosis patients are consistent with this latter possibility.

Over 50% of all patients with sarcoidosis have remission of their disease. The determinants of this outcome are unknown. One study found that patients with active sarcoidosis who underwent spontaneous remission within 6 months had significantly greater production of transforming growth factor- β (TGF- β) from cultured BAL cells at the time of initial evaluation than did patients who later required therapy or who demonstrated progressive disease.¹⁸ Because TGF- β is a potent endogenous inhibitor of IL-12 and CD4 Th1 development, these observations suggest that TGF- β may downregulate Th1-driven granulomatous responses in sarcoidosis in the absence of persistent antigenic stimulation. Two studies have found reduced numbers of immunoregulatory CD1d-restricted V α 24 NKT cells in the blood of patients with nonremitting sarcoidosis, suggesting a deficiency of these cells may play a role in chronic sarcoidosis. Another study reports that immunoregulatory CD4⁺CD25(bright)FoxP3⁺ T cells accumulate at the periphery of sarcoidosis granulomas, in BAL fluid, and in peripheral blood of patients with active disease.²⁰ These T regulatory (Treg) cells exhibited powerful antiproliferative activity *in vitro*, yet did not completely inhibit TNF- α production, suggesting that an expanded Treg population was insufficient to control local inflammation but could account for the cutaneous anergy that is typical in sarcoidosis.

PATIENT EVALUATION AND DIFFERENTIAL DIAGNOSIS

PULMONARY SARCIDOSIS

The most common symptoms of pulmonary sarcoidosis are progressive shortness of breath, nonproductive cough and ill-defined, variably severe chest discomfort (Table 72.1). Chronic sputum production and hemoptysis are more frequent in advanced fibrocystic disease. Typically, there are few physical findings in pulmonary sarcoidosis. Lung crackles are heard in fewer than 20% of patients and clubbing is rare. Findings of pulmonary hypertension or cor pulmonale are seen in 1–4% of patients, usually those with severe fibrocystic sarcoidosis or, rarely, a granulomatous vasculitis of the pulmonary vessels.

Chest radiographs are abnormal in more than 90% of patients with sarcoidosis. By international convention, the chest radiograph is divided into the following stages or types:

Stage 0: normal chest radiograph

Stage I: bilateral hilar adenopathy

Stage II: bilateral hilar adenopathy + interstitial infiltrates

Stage III: interstitial infiltrates only (nonfibrotic)

Stage IV: fibrocystic interstitial lung disease

A normal chest X-ray is found in 5–10% of patients with sarcoidosis. Stage I changes are seen in 40–50% of cases at presentation. Typically, the hilar adenopathy is discrete, symmetric, and often accompanied by right paratracheal adenopathy. A stage II chest radiograph, often with mid- or

upper-zone infiltrates, is initially seen in 20–30% of cases (Fig. 72.3). A stage III radiograph is initially seen in 10–20% of cases. Chest radiographs with fibrocystic changes and scarring are rare at presentation and carry a poor outcome (Fig. 72.4). Mycetomas are mobile fungus balls that colonize pre-existing cystic spaces in fibrocystic sarcoidosis. More unusual patterns of pulmonary sarcoidosis include large, well-defined nodular infiltrates, miliary disease, or a pattern of patchy airspace consolidation with air bronchograms, termed “alveolar sarcoidosis.” Pleural effusions and pneumothorax are rare.

Computed tomography (CT) of the chest is more sensitive than plain radiography in demonstrating enlarged lymph nodes and pulmonary infiltrates. Chest CT typically demonstrates nodular infiltrates that follow central bronchovascular structures (Fig. 72.5).

Pulmonary function tests do not correlate well with chest radiographs. In patients with stage I chest radiographs pulmonary function tests are normal in about 80% of cases, or have only an isolated reduction in diffusing capacity for carbon monoxide (DLco). When pulmonary infiltrates are present on chest radiography, restrictive impairment with reduction in lung volumes, forced vital capacity and forced expiratory volume in 1 second, or a reduction in DLco is found in 40–70% of cases. Obstructive impairment is found in <30–50% of patients, most often in advanced fibrocystic sarcoidosis. Bronchial hyperreactivity is present in 10–30% of patients. Gas exchange is usually preserved unless extensive fibrotic changes are evident.

Fig. 72.3 Chest radiograph demonstrating a stage II pattern with bilateral hilar adenopathy and reticulonodular infiltrates.

Fig. 72.4 Fibrocystic (stage IV) pulmonary sarcoidosis with typical upward hilar retraction and multiple cystic and bullous changes.

Fig. 72.5 Computed tomography scan of the chest in a patient with biopsy-proven pulmonary sarcoidosis, demonstrating bilateral hilar, paratracheal, and para-aortic lymphadenopathy with interstitial infiltrates in a dominantly central bronchovascular distribution.

EXTRAPULMONARY SARCOIDOSIS

Most patients have clinically important involvement of more than one organ, either with or without pulmonary sarcoidosis (Table 72.1).²¹ Rare manifestations are usually the result of either an uncommon pattern of systemic involvement or granulomatous inflammation developing in an unusual location for sarcoidosis.²²

SARCOIDOSIS OF THE UPPER RESPIRATORY TRACT

Sarcoidosis of the upper respiratory tract occurs in approximately 5–10% of patients, usually those with long-standing disease. Involvement of the mucosa of the nasal septum, inferior turbinates, and nasopharynx may lead to nasal congestion, dizziness, crusting, epistaxis, anosmia, or rhinorrhea. Nasal septal perforation, a ‘saddle-nose’ deformity, or palatal perforation or bone erosion may occur, particularly in patients with previous submucous resections. Sarcoidosis may affect the maxillary, ethmoid, and sphenoid sinuses, leading to obstruction and sinusitis. Laryngeal sarcoidosis is an uncommon feature, occurring in <1–5% of patients. Patients may manifest with hoarseness, dysphonia, dysphagia, dyspnea or, rarely, stridor and acute respiratory failure.

OCULAR SARCOIDOSIS

Unilateral or bilateral anterior uveitis is the most common ocular manifestation of sarcoidosis and is often associated with bilateral hilar adenopathy. Chronic uveitis occurs in as many as 20% of patients with chronic sarcoidosis, more frequently in black populations. Other manifestations include posterior uveitis, granulomatous conjunctivitis or severe chorioretinitis, or optic neuritis; these latter conditions may present acutely with blindness.

CUTANEOUS SARCOIDOSIS

Erythema nodosum is a component of Löfgren syndrome, and may recur. Chronic skin sarcoidosis usually manifests as nontender, nonpruritic plaques and subcutaneous nodules around the hairline, eyelids, ears, nose, mouth, and the extensor surfaces of the arms and legs. Lupus pernio is a particularly disfiguring form of cutaneous sarcoidosis of the face, with violaceous plaques and nodules covering the nose, nasal alae, malar areas, and around the eyes.

CARDIAC SARCOIDOSIS

Cardiac sarcoidosis is clinically apparent in <5–10% of patients with sarcoidosis in North America and Europe, though autopsy studies suggest up to 25% may be affected. In Japan, cardiac involvement may be present in >50% of patients. Complete heart block is the most common manifestation; other less common patterns include ventricular arrhythmias, bundle-branch blocks, sudden death, cardiomyopathy, supraventricular arrhythmias, and valvular dysfunction. Most deaths due to cardiac sarcoidosis are caused by arrhythmias, heart block, or congestive heart failure.²³

HEPATIC SARCOIDOSIS

Symptomatic hepatic sarcoidosis manifests with fever, tender hepatomegaly, or intense pruritus. Characteristically, the serum alkaline phosphatase and γ -glutamyltransferase are elevated proportionately higher than the aspartate aminotransferase (AST) and alanine aminotransferase (ALT) and bilirubin, though all patterns can be seen. Hepatic sarcoidosis may mimic primary biliary cirrhosis, except that antimitochondrial antibodies are absent. The term ‘abdominal sarcoidosis’ is often used for patients manifesting with liver, spleen, and abdominal lymph node involvement, often with hypercalcemia; pulmonary involvement may not be evident.

JOINTS AND BONES

Arthralgias are common in active multisystem sarcoidosis, although joint radiographs are usually negative. Acute, often incapacitating, migratory polyarthritis involving the ankles, feet, knees, and wrists may be seen in Löfgren syndrome. Persistent joint disease is found in fewer than 5% of patients with chronic sarcoidosis. Pain, swelling, and tenderness of the phalanges of the hands and feet are the commonest symptoms. Joint radiographs may demonstrate ‘punched-out’ lesions with cystic changes and marked loss of trabeculae but without evidence of erosive chondritis. Cystic lesions of the long bones, pelvis, sternum, skull, and vertebrae rarely occur.

NEUROSARCOIDOSIS

Neurosarcoidosis occurs in approximately 5% of sarcoidosis patients.²⁴ The most common manifestation is cranial neuropathy, with bilateral or unilateral seventh-nerve (Bell’s) palsy or, less commonly, glossopharyngeal, auditory, oculomotor, or trigeminal palsies. The palsy may resolve spontaneously or with corticosteroids, but sometimes recurs years later. Optic neuritis can result in blurred vision, field defects, and blindness. Manifestations of central nervous system (CNS) involvement include mass lesions, aseptic meningitis, obstructive hydrocephalus, and hypothalamic/pituitary dysfunction. Seizures, headache, change in mental status, confusion, and diabetes insipidus may be presenting symptoms. Spinal cord compression syndromes are rare, but paraparesis, hemiparesis, and back and leg pain have been described. Peripheral neuropathies account for about 15% of cases of neurosarcoidosis, often presenting as mononeuritis multiplex or a primary sensory neuropathy. Small-fiber neuropathy occurs frequently in sarcoidosis, particularly in chronic disease. A subset of patients meets diagnostic criteria for fibromyalgia. Both conditions may be associated with pain that is resistant to anti-inflammatory drugs.

SALIVARY, PAROTID, AND LACRIMAL GLAND SARCOIDOSIS

Parotid or lacrimal gland enlargement or sicca syndrome can occasionally be the dominant clinical manifestations of sarcoidosis. Herefordt syndrome, also known as uveoparotid fever, manifests as fever, parotid and lacrimal gland enlargement, uveitis, and bilateral hilar adenopathy. This uncommon presentation of acute sarcoidosis can be associated with cranial neuropathies, usually facial palsy.

HEMATOLOGIC SARCOIDOSIS

Peripheral lymph node enlargement occurs in 20–30% of patients as an early manifestation of sarcoidosis, but then typically undergoes spontaneous remission. Persistent, bulky lymphadenopathy occurs less than 10% of the time. Splenomegaly, occasionally massive, occurs in fewer than 5% of cases and is often associated with hepatomegaly or hypercalcemia. Nonclonal hypergammaglobulinemia is present in 25% or more of patients.

SARCOIDOSIS MYOPATHY

Although muscle granulomas can be found at autopsy in most sarcoidosis patients, symptomatic myopathy with weakness and tenderness is uncommon. Rarely, sarcoidosis presents as a polymyositis with profound weakness and elevated serum creatine kinase and aldolase.

HYPERCALCEMIA, HYPERCALCIURIA, AND RENAL DISEASE

Hypercalcemia is present in 2–5% of patients; hypercalciuria is more common. Abnormal calcium regulation is thought to be due to an increased conversion of 1-hydroxy (OH) vitamin D₃ to active 1,25-(OH)₂ vitamin D₃ by macrophages and epithelioid cells from granulomas. Chronic hypercalcemia or hypercalciuria most commonly manifests as kidney stones. Renal failure from chronic clinically silent nephrocalcinosis can occur. Granulomatous involvement of the kidneys is uncommon and usually not a cause of renal failure.

PSYCHOSOCIAL MANIFESTATIONS

Depression has been found in 30–60% of symptomatic patients with sarcoidosis. In the ACCESS study, depression was associated with female sex, lower socioeconomic status, poor access to care, and increased disease severity, but not race.

ASSOCIATED CONDITIONS

Sarcoidosis and pregnancy

Usually pregnancy has little effect on the course of sarcoidosis, although some patients experience spontaneous improvement. In those who improve, exacerbation frequently follows several months after delivery. The reasons for the temporary clinical improvement are not known but might be related to suppressed Th1 immunity during pregnancy.

Th1-promoting therapeutics

The administration of Th1-promoting therapeutics such as IFN- α , IFN- γ , IL-2, and IFN- β may be associated with initiation or recrudescence of sarcoidosis.

Common variable immunodeficiency

Sarcoidosis is associated with common variable immunodeficiency (CVID) in both adult and pediatric sarcoidosis. A high index of suspicion must be maintained for CVID in sarcoidosis patients who have recurrent infections or in any child with sarcoidosis, given the low frequency of sarcoidosis in this age group.

Human immunodeficiency virus (HIV)

Sarcoidosis may develop in HIV-infected patients with immune reconstitution following initiation of highly active antiretroviral therapy, perhaps from reconstituted Th1 immunity. Granulomatous inflammation of the lungs or skin is the commonest presentation.

Autoimmune disorders

Sarcoidosis has been described in association with autoimmune diseases such as Crohn disease, ulcerative colitis, primary biliary cirrhosis, scleroderma, Sjögren syndrome, autoimmune hemolytic anemia, and autoimmune endocrinopathies. These associations could be the result of a common, predisposing altered Th1 immunity.

Cancer

Epithelioid granulomas are reported in ~3–10% of tumors and in ~4% of regional draining lymph nodes. Much less commonly, multisystem sarcoidosis can develop in patients with a recent or past diagnosis of cancer or following chemotherapy treatment. Several cases of sarcoidosis have developed in patients with 5q-myelodysplasia that results in deletion of several Th2 genes (IL-4, IL-13, colony-stimulating factor-2) that probably lead to dysregulated Th1/Th2 immunity.

DIAGNOSIS

A diagnosis of sarcoidosis is based on a compatible clinical picture, histologic evidence of noncaseating granulomas, and the absence of other known causes of this pathologic response.² Tuberculosis, fungal disease, and lymphoma are the most important diseases to be excluded in patients with chest disease. Chronic beryllium disease and hypersensitivity pneumonitis must be excluded when there is a compatible history and clinical findings are confined to the lung. In the absence of defined multisystem disease a diagnosis of sarcoidosis should be presumed, as local 'sarcoid' reactions may occur in response to infection, tumor, or foreign material. Biopsy confirmation of sarcoidosis is not usually necessary in Löfgren syndrome, except in regions where histoplasmosis is endemic.

In general, biopsy of the easiest, most accessible abnormal tissue site is used to confirm the diagnosis. Biopsy of a skin nodule, superficial lymph node, lacrimal gland, nasal mucosae, conjunctivae, or salivary gland (lip biopsy) may establish a diagnosis. Biopsy of the liver or bone marrow is nonspecific and should be used to support a diagnosis of sarcoidosis only after malignancy, infectious granulomatous diseases, or other organ-specific diagnoses have been excluded. Imaging techniques such as ¹⁸F-fluorodeoxyglucose (FDG)-positron emission tomography (PET) scanning or gallium-67 scanning are occasionally helpful in defining appropriate sites for biopsy.

Biopsy by fiberoptic bronchoscopy is frequently used to diagnose pulmonary sarcoidosis because of its relative safety and high yield. The yield of transbronchial biopsy is operator-dependent, but approaches 80–90% when pulmonary infiltrates are seen radiographically (Figs 72.3–72.5). Bronchial or transbronchial needle aspiration biopsies may increase the yield further. Mediastinoscopy or thoracoscopic or surgical lung biopsy should be considered when lymphoma or other intrathoracic malignancy cannot be reasonably excluded.

The initial diagnostic evaluation of a patient with possible sarcoidosis should include tests to evaluate the presence and extent of pulmonary involvement and screen for extrathoracic disease.² In the presence of cardiac symptoms, two-dimensional echocardiography and 24-hour electrocardiograph recording are indicated. Radionuclide imaging with gated 201-thallium or technetium-99m sestamibi has greater sensitivity in detecting segmental areas of decreased uptake that correspond to areas involved with granulomatous inflammation or fibrosis. When uncertainty persists, cardiac magnetic resonance or cardiac PET have even greater theoretical resolution, but are nonspecific and there is limited experience in sarcoidosis. A diagnosis of cardiac sarcoidosis is usually made clinically, with biopsy confirmation of a noncardiac site. Endomyocardial biopsy is positive in <10–25% of cases of cardiac sarcoidosis, owing to the patchiness of the granulomatous inflammation; thus, a negative biopsy never excludes the diagnosis.

When CNS sarcoidosis is considered, magnetic resonance imaging (MRI) with gadolinium enhancement is now considered the optimal test to detect the characteristic inflammatory lesions that have a propensity for periventricular and leptomeningeal areas.²⁴ A normal scan does not exclude neurosarcoidosis, particularly for cranial neuropathies or while taking corticosteroids. Cerebrospinal fluid characteristically demonstrates lymphocytic pleocytosis and/or elevated protein levels. A diagnosis of neurosarcoidosis is usually confirmed by biopsy of a non-CNS site, generally by bronchoscopic or lymph node biopsy. Rarely, brain biopsy is

CLINICAL PEARLS

TESTS RECOMMENDED FOR AN INITIAL EVALUATION OF A PATIENT WITH SARCOIDOSIS

- >> Chest radiograph
- >> Pulmonary function tests
 - Spirometry
 - Diffusing capacity
 - Lung volumes
 - Flow-volume loop (if suspected upper-airway obstruction)
- >> Slit-lamp examination (to exclude subclinical uveitis)
- >> Liver and renal function tests
- >> Calcium level
- >> Complete blood count
- >> Electrocardiogram
- >> Purified protein derivative skin test
- >> Organ-specific testing for symptomatic involvement

needed to exclude infectious or malignant disease. In suspected cases of peripheral neuropathy or myopathy, electromyogram or nerve conduction studies should be considered.

OTHER DIAGNOSTIC STUDIES

There are no noninvasive tests that have been shown to be useful in assisting the clinician in making a diagnosis of sarcoidosis. Serum ACE (SACE) levels are elevated in 40–90% of patients with clinically active disease, but may be found in other granulomatous diseases and in some nongranulomatous conditions, such as hyperthyroidism, hepatic cirrhosis, diabetes mellitus, and Hodgkin disease. This lack of specificity limits the use of SACE in confirming a diagnosis of sarcoidosis.^{2,3} Although > 90% of nonsmoking patients with pulmonary sarcoidosis have increased proportions of CD4 BAL T cells, typically with a CD4:CD8 ratio of 3–10:1 compared to 2:1 in healthy individuals, these findings are not sufficiently specific to establish a diagnosis of sarcoidosis.^{2,3}

PREVENTION AND PATIENT MANAGEMENT

The clinical course of sarcoidosis is highly variable.^{2,4} Overall, 50–65% of patients undergo spontaneous remission, usually (> 85%) within the first 2 years. The prognosis is best for those with Löfgren syndrome, 70–80% of whom have a spontaneous remission. Peripheral adenopathy, salivary and parotid gland enlargement, and Bell palsy generally subside spontaneously or with treatment, and do not recur. Elevated serum liver function tests can also revert to normal without treatment. The rate of spontaneous remission in pulmonary sarcoidosis differs according to the initial chest X-ray pattern. Approximately 50–80% of patients with a stage I chest radiograph have remission, whereas 30–60% with a stage II radiograph and 20–30% with a stage III radiograph undergo remission.

Patients with a stage IV chest radiograph with fibrocystic changes rarely (< 5%) undergo remission. Extrapulmonary disease that is symptomatic and severe on presentation tends to persist and require treatment. Patients with lupus pernio, bony involvement, nephrocalcinosis, and splenomegaly rarely undergo spontaneous remission.

The intensity of surveillance of sarcoidosis depends on the severity of clinical presentation, but should include serial tests of organ-specific function. When sarcoidosis undergoes remission, the disease rarely recurs; exceptions often involve neurologic or ocular manifestations. Noninvasive tests such as BAL, SACE, and other biochemical measurements have not been shown to be useful in management decisions.^{2,3}

TREATMENT

Corticosteroids remain the mainstay of therapy for serious or progressive pulmonary or extrapulmonary sarcoidosis.^{2,3} Corticosteroids provide symptomatic relief acutely and reverse organ dysfunction in > 90% of patients with symptomatic disease. Although there is controversy regarding their overall effectiveness in altering the long-term course of the disease, there is widespread agreement that early treatment is indicated for serious pulmonary or extrapulmonary disease. When the condition is not serious or organ-threatening, a period of observation is often indicated to evaluate whether the patient will undergo spontaneous remission.

The optimal doses and duration of corticosteroid treatment have not been established by rigorous clinical studies. Initial treatment with corticosteroids usually employs no more than 20–40 mg/day of prednisone for 2–4 weeks, followed by a slow tapering regimen over several months to a maintenance dose of 5–15 mg/day.²⁵ Alternate-day therapy is suggested by some investigators, although such a regimen may not be effective in a subgroup of patients who then respond to daily dosing. Treatment is ordinarily continued for a minimum of 8–12 months, as premature tapering is likely to result in relapse. Recurrent, progressive pulmonary disease occurs in 16–74% of patients as corticosteroid therapy is tapered; those patients with repetitive relapses usually benefit from indefinite suppressive therapy to minimize loss of lung function.²⁶ Inhaled corticosteroids may be helpful in reducing symptoms of endobronchial sarcoidosis, such as cough or airway irritability, but have not been proven useful as sole agents in pulmonary sarcoidosis, except possibly in mild disease.

Low-dose corticosteroid therapy is often well tolerated, although weight gain, hypertension, hyperglycemia, glaucoma, and osteoporosis are serious complications. Because of the risk of hypercalcemia and hypercalciuria, supplemental calcium and vitamin D are not routinely given. Bisphosphonate therapy is often recommended for documented osteoporosis, but clinical studies of their efficacy in sarcoidosis are lacking.

SPECIFIC SITUATIONS

LÖFGREN SYNDROME

Nonsteroidal anti-inflammatory drugs are recommended for the relief of constitutional symptoms and joint pains. For disabling arthritis or severe constitutional symptoms, corticosteroids are almost immediately effective. Generally, the steroids can be tapered over a few weeks to months without recrudescence of symptoms.

THERAPEUTIC PRINCIPLES

INDICATIONS FOR CORTICOSTEROID THERAPY IN PATIENTS WITH SARCOIDOSIS

- >> Pulmonary involvement
 - Moderate or severe, symptomatic pulmonary disease
 - Progressive, symptomatic pulmonary disease
 - Persistent pulmonary infiltrates or abnormal lung function for 1–2 years with mild symptoms to assess reversibility
 - Advanced fibrocystic disease
- >> Extrapulmonary involvement
 - Threatened organ failure: severe ocular, cardiac, or central nervous system disease
 - Posterior uveitis or anterior uveitis not responding to local steroids
 - Persistent hypercalcemia
 - Persistent renal or hepatic dysfunction
 - Pituitary disease
 - Myopathy
 - Palpable splenomegaly or evidence of hypersplenism such as thrombocytopenia
 - Severe fatigue and weight loss
 - Painful lymphadenopathy
 - Disfiguring skin disease

OCULAR SARCOIDOSIS

Anterior uveitis can often be treated effectively with topical corticosteroids alone. Oral corticosteroids are usually necessary for posterior uveitis, chorioretinitis, and optic neuritis. The latter two may present as ocular emergencies requiring high doses of intravenous corticosteroids initially.

CARDIAC SARCOIDOSIS

Treatment consists of antiarrhythmic therapy, diuretics, and afterload-reducing agents for heart failure, in addition to anti-inflammatory drugs. Corticosteroids are recommended in moderate doses since such treatment is associated with improved cardiac function and outcomes and may reverse heart block or reduce arrhythmias.²⁷ Initial therapy often begins with prednisone 40–60 mg/day, followed by a slow taper to a maintenance dose of 10–20 mg/day. Automatic implantable defibrillators or pacemakers are indicated in patients at risk for sudden death from serious arrhythmias or heart block, though indications for their prophylactic placement have not been established.

NEUROSARCOIDOSIS

High doses of oral corticosteroids (60–80 mg/day) or high-dose pulse intravenous therapy are often employed for serious CNS involvement.²⁴ Tapering should be performed over several months after evidence of

suppression of inflammation by objective criteria (e.g., serial MRI scans). With the exception of cranial neuropathies, neurosarcoidosis tends to be chronic and requires long-term therapy.

ALTERNATIVE THERAPIES

Alternative therapies are frequently employed for chronic, progressive sarcoidosis when corticosteroid adverse effects significantly degrade quality of life.²⁸ None of these therapies has been proven effective by rigorous clinical trials. Large case series suggest these therapies are effective in only subsets of patients, and may require concomitant corticosteroid therapy.

ANTI-INFLAMMATORY THERAPIES

Hydroxychloroquine is often tried as a first-line treatment for mucocutaneous disease, including lupus pernio, other disfiguring skin disease, and nasal, sinus, and laryngeal sarcoidosis when corticosteroids are not immediately needed. The beneficial effects may not be evident for 2–3 months, with an overall 40–50% response rate. Hydroxychloroquine is often tried as a potential steroid-sparing drug for pulmonary or systemic disease, though with lower effectiveness. Chloroquine may be effective in some patients unresponsive to hydroxychloroquine, but has a greater potential for ocular toxicity and requires periodic drug-free intervals.

Pentoxifylline, a phosphodiesterase inhibitor, was found to be beneficial in one study of mild pulmonary sarcoidosis, though wider experience suggests only a small minority of patients respond. Gastrointestinal side effects often limit the dose that is tolerated.

Small case series suggest that thalidomide may be beneficial in severe cutaneous sarcoidosis, including lupus pernio. However, the drug does not appear to be effective for pulmonary disease. Peripheral neurotoxicity and the well-known teratogenicity of the drug mandate careful patient selection.

The tetracyclines, minocycline and doxycycline, have been reported to be effective in a small number of patients with cutaneous sarcoidosis and even less frequently as a steroid-sparing drug in pulmonary sarcoidosis. These antibiotics have anti-inflammatory effects that likely explain their mechanism of action as other antibiotics have not been found effective in sarcoidosis.

IMMUNOSUPPRESSIVE THERAPIES

Mathotrexate in low weekly doses (10–20 mg/day) is often used as an alternative therapy in corticosteroid-recalcitrant pulmonary, cardiac, ocular, cutaneous, and neurologic sarcoidosis.²⁸ Success rates range from 50% to 70% as a corticosteroid-sparing drug, but it may take 6 months or longer to show effectiveness. Potential serious complications include hepatotoxicity, opportunistic infections, bone marrow suppression, and pulmonary toxicity.

Limited clinical studies suggest that azathioprine in a dose of 100–200 mg/day may be useful in corticosteroid-recalcitrant sarcoidosis, often combined with low doses of corticosteroids. More recently, mycophenolate mofetil has been used with anecdotal benefit and, possibly, an improved safety profile over azathioprine. Beneficial effects are usually apparent by 2–4 months. Potential drug toxicities include bone marrow suppression, gastrointestinal symptoms, skin rashes, arthralgias, and possibly a slightly increased risk of malignancy. There are some anecdotal

reports of using cyclophosphamide in steroid-recalcitrant sarcoidosis, particularly refractory neurosarcoidosis, though its use is severely limited because of its oncogenic potential.

Cyclosporine, a drug known to inhibit T-cell activation, appears to be ineffective, except possibly in a few cases of severe neurosarcoidosis.

ANTI-TNF INHIBITORS

The use of TNF inhibitors in sarcoidosis is based on the established role of TNF in experimental models of granuloma formation. One recent multicenter study found infliximab to have a modest effect on one of several primary endpoints (improved forced vital capacity after 24 weeks of therapy).²⁹ Anecdotal cases suggest adalimumab may also be effective, but etanercept was ineffective in a small clinical trial. Risks of these therapies include allergic reactions and infectious complications, including sepsis and reactivation tuberculosis. Given these risks, further clinical trials are needed before these therapies could be routinely recommended in sarcoidosis.

ROLE OF TRANSPLANTATION IN SARCOIDOSIS

Lung, heart, kidney, and liver transplantations have been performed successfully in small numbers of patients with sarcoidosis. Recurrent granulomas are found in the transplanted organs of some patients but are generally transient, self-limited, and responsive to an increase in immunosuppression. Pulmonary hypertension is an independent predictor of reduced survival in patients with advanced pulmonary sarcoidosis awaiting lung transplantation.³⁰ Overall, the survival rate for lung transplantation for end-stage pulmonary sarcoidosis appears to be similar to that of other organ-specific diseases.

INFORMATION FOR PATIENTS

An updated primer on sarcoidosis sponsored by the US National Heart, Lung and Blood Institute is available on the internet for interested patients and physicians.³¹

Immunologic ocular disease

James T. Rosenbaum, Matthias D. Becker,
Justine R. Smith

73

The immune system can induce disease in virtually any portion of the eye. Examples include conjunctivitis, keratitis, keratoconjunctivitis, uveitis, scleritis, optic neuritis, and orbital inflammation. The anatomy of the eye is depicted schematically in [Figure 73.1](#). Two relatively common immunologically mediated ocular diseases discussed elsewhere in this volume are sicca syndrome secondary to Sjögren's syndrome (Chapter 54) and anterior ischemic optic neuropathy secondary to giant cell arteritis (Chapter 59). Before considering those additional ocular disorders that are the most common and visually significant, it is critical to review some unique considerations related to ocular immunology.

■ OCULAR IMMUNE PRIVILEGE ■

Many of the mechanisms that drive inflammation in the eye are identical to those operating at other tissue sites. The major difference between the immunopathology of intraocular inflammation and that of systemic inflammatory disease relates to the fact that the eye, like the brain and the testis, is an immunologically privileged site. During uveitis, keratitis, and scleritis, as well as following corneal transplantation, a variety of local immunosuppressive mechanisms act to limit the damage caused by infiltrating leukocytes, and, consequently, to influence the patient's clinical course. One of the most important factors is the constitutive expression of Fas ligand (FasL) within the eye. In addition, normal ocular tissues produce relatively high levels of immunomodulatory cytokines and immunosuppressive neuropeptides, as well as complement regulatory proteins. Other factors include the blood–aqueous and blood–retinal anatomical barriers, limited MHC expression, a paucity of lymphatic drainage channels within the eye, and, in the case of the cornea, the complete absence of blood vessels. Anterior chamber-associated immune deviation (ACAID) describes the suppression of a cell-mediated immune response when soluble antigen is directly injected into the aqueous humor. ACAID presumably results from some or all of the above factors.

■ FAS LIGAND ■

Many immune cells, including neutrophils, monocytes, macrophages and lymphocytes, express Fas (CD95) on their surface. The interaction between Fas and its receptor FasL (CD95L) triggers apoptosis of the Fas-bearing cell. FasL is constitutively expressed within the eye, being detected in normal cornea, anterior uvea and retina. The importance of FasL to ocular immune privilege has been demonstrated primarily in experimental models of ocular inflammation. Corneal allografts from FasL-negative mice into recipients of normal phenotype are rejected in all cases, whereas approximately half of FasL-positive grafts survive.¹ When injected into the eyes of FasL-deficient mice, herpes simplex virus causes a severe invasive infection. A similar procedure in normal phenotype control animals results in relatively minor inflammation. Levels of FasL in aqueous humor during human acute anterior uveitis are capable of inducing apoptosis in Fas-positive lymphoid cells. In this self-limiting condition, as well as in relevant rodent models, apoptosis of infiltrating T cells is observed early in the course of the inflammation. In addition to FasL, the local expression of TRAIL (TNF-related apoptosis-inducing ligand) by corneal endothelium also contributes to enhanced apoptosis and immune privilege within the eye.²

■ CYTOKINE NETWORK, NEUROPEPTIDES AND COMPLEMENT ■

Tissues in both the anterior and the posterior segments of the human eye constitutively express the immunomodulatory cytokine transforming growth factor- β (TGF- β).³ The concentration of TGF- β in the aqueous humor is sufficient to inhibit T-cell activation and proliferation in a variety of assays.⁴ As might be anticipated, significantly lower levels of this activated cytokine are measured in the aqueous of patients with a variety

Fig. 73.1 Schematic representation of the eye.

of uveitis syndromes compared to levels present in normal eyes. The inflammatory cytokine interleukin (IL)-1 has been implicated in the pathogenesis of various ocular inflammatory diseases. There is expression of IL-1 receptor antagonist (IL-1Ra) in normal cornea⁵ and retinal pigment epithelium, implying that this tissue contains a control mechanism for responses mediated by IL-1. Interestingly, topical application of IL-1Ra has a significantly positive effect in promoting experimental corneal allograft survival. The aqueous humor contains neuropeptides, including α -melanocyte stimulating hormone, vasoactive intestinal peptide and calcitonin gene-related peptide, that inhibit the activities of T cells and macrophages. Complement is active at low levels in the healthy eye, regulated by complement regulatory proteins that are expressed both on intraocular cell membranes and within the intraocular fluid; this system may participate in the destruction of pathogens invading the eye.⁶ However, interestingly, iC3b, generated because of this activation, appears to inhibit antigen-specific delayed type hypersensitivity.

■ ANTERIOR CHAMBER-ASSOCIATED IMMUNE DEVIATION ■

Anterior chamber-associated immune deviation is 'a stereotypic, systemic immune response to antigens placed in the anterior chamber (of the eye) in which delayed hypersensitivity is avoided and suppressed.' The molecular events that are responsible for this phenomenon include the following:⁷ Entry of an antigen into the eye stimulates production of tumor necrosis factor- α , and hence the upregulation of cell adhesion molecules; secretion of IL-10 by the infiltrating T cells; and sensitization of these cells for FasL-mediated killing. TGF- β also induces ocular antigen-presenting cells to secrete IL-10 during antigen processing.⁸ Apoptotic T cells pass in the bloodstream to the spleen, where they are phagocytosed and induce activation of Th2-type CD4 T cells. The Th2-type cells control Th1 function by secreting various immunomodulatory cytokines. T-cell receptor α -chain fragments from apoptotic cells are presented in the class I pathway. This event generates CD8 killer cells, which are capable of deleting the CD4 T cells that would otherwise mediate a delayed-type hypersensitivity response. CD8 T cells that

secrete immunomodulatory cytokines, including IL-10 and TGF- β , are also generated. ACAID is also dependent on the presence of invariant natural killer T cells.

■ IMMOBILITY OF DENDRITIC CELLS WITHIN THE ANTERIOR CHAMBER ■

A recently appreciated phenomenon within the iris is that the vast majority of cells that phagocytose foreign antigen fail to migrate after antigen uptake. This is clearly demonstrable by intravital microscopy and correlates with the failure of these antigen-bearing cells to migrate to the local lymph nodes.⁹ The inability to migrate is consistent with the known lack of lymphatics within the eye, and must mean that soluble antigen injected into the anterior chamber is not presented in the regional lymph node in a manner that is comparable to what follows antigen exposure in an organ such as the skin.

■ UVEITIS ■

UVEITIS AS A DIAGNOSTIC ENTITY

The uveal tract is the middle layer of the eye, divided into the anterior uvea (iris, ciliary body) and posterior uvea (choroid). The uvea is sandwiched between an outer layer (sclera) and an inner layer (retina). The anterior segment is separated from the posterior segment by the lens. Uveitis is an extremely variable spectrum of different diseases that includes a variety of infections and immune-mediated diseases (Table 73.1). It is the third leading cause of preventable blindness worldwide. Inflammatory disorders of the retina (retinitis) and sclera (scleritis) frequently involve the adjacent uveal tract. Many different immune mechanisms could result in uveitis, as evidenced in animal models. These mechanisms include an immune response to a sequestered self-antigen, molecular mimicry, immune complex deposition, and the response to a toxin.

The differential diagnosis of uveitis is facilitated by identifying characteristic clinical features. Uveitis can be classified by location: anterior (iritis, iridocyclitis), intermediate (pars planitis, vitritis) or posterior (retinitis, choroiditis, retinochoroiditis, chorioretinitis, retinal vasculitis). Some forms of uveitis involve all portions of the uveal tract (panuveitis). Uveitis can be classified by course (self-limited, chronic, or recurrent); by onset (sudden, insidious); by symmetry (unilateral, bilateral); by associated complications such as glaucoma, cystoid macular edema (Figs. 73.2–73.4), synechiae (for example, adhesion of the iris to the lens) (Fig. 73.5), retinal detachment, or band keratopathy (the deposition of calcium in the epithelium of the cornea) (Fig. 73.6); and by the appearance of inflammatory keratic precipitates on the endothelium of the cornea within the eye (granulomatous, nongranulomatous) (Fig. 73.7). Granulomatous diseases with large cellular concretions on the cornea or nodules within the iris include tuberculosis, syphilis, sarcoidosis, Vogt-Koyanagi-Harada disease and sympathetic ophthalmia. The group of nongranulomatous diseases includes ankylosing spondylitis, reactive arthritis, and juvenile idiopathic arthritis. Table 73.2 shows how these parameters contribute to the differential diagnosis. Additionally, ethnic and geographic considerations factor into the differential diagnosis. For example sarcoidosis, Behçet' syndrome, and Vogt-Koyanagi-Harada

Table 73.1 Diagnostic categories of uveitis

Diagnostic group		Diagnosis
Infectious Causes	Viral	Herpes simplex Herpes zoster Cytomegalovirus HTLV-1 Mumps West Nile
	Bacterial or spirochetal	Atypical Mycobacterium Bacterial endocarditis Bartonella Brucellosis Leprosy Leptospirosis Lyme disease Propionibacterium Tuberculosis Leprosy Syphilis Whipple's disease
	Parasitic (protozoan or helminthic)	Acanthameba Cysticercosis Onchocerciasis Pneumocystis carinii Toxoplasmosis Toxocariasis
	Fungal	Histoplasmosis Coccidioidomycosis Candidiasis Aspergillosis Sporotrichosis Blastomycosis Cryptococcosis
Immune Mediated		Ankylosing spondylitis Behçet's disease Crohn's disease Drug or hypersensitivity reaction (such as rifabutin or cidofovir) Familial granulomatous synovitis with uveitis Interstitial nephritis Juvenile idiopathic arthritis Kawasaki disease Multiple sclerosis Psoriatic arthritis Reactive arthritis Relapsing polychondritis Rheumatic fever Sarcoidosis Scleritis Sjogren's syndrome Sweet's syndrome Systemic lupus erythematosus

Fig. 73.3 Ocular coherence tomogram (OCT). This is an image of a normal eye. An OCT allows precise quantification of macular thickening. In this image, the macula shows a normal dipole or indentation.

Fig. 73.4 OCT image showing marked macular edema. The macula is markedly elevated.

disease have strong ethnic predispositions, whereas certain infections such as cytomegalovirus in association with AIDS, leprosy, or onchocerciasis vary in prevalence based on geographic area. Together with a medical history, gender, and age, these findings help to narrow the differential diagnosis of uveitis.

The following case vignettes illustrate how important a precise and critical history and examination are. A 22-year-old man with low back pain and a red painful eye due to episodic, unilateral, sudden onset anterior uveitis is highly likely to have a spondyloarthropathy (Chapter 57). A 6-year-old girl with no ocular complaints but biomicroscopic findings of bilateral band keratopathy and leukocytes in the anterior chamber is likely to suffer from the pauciarticular subset of juvenile idiopathic arthritis (Chapter 53).

The most obvious sign of uveal inflammation is the presence of biomicroscopically visible leukocytes in the anterior or the posterior chamber of the eye. Most patients with anterior uveitis will experience pain, redness, photophobia, miosis and a variable degree of visual loss. In contrast, many forms of uveitis that affect the posterior segment will cause no redness, no pain, no change in pupil size (no macroscopically apparent signs of an inflamed eye). Instead, disturbances in visual acuity may vary from normal vision to seeing floaters, to blurred vision to blindness.

EPIDEMIOLOGY

The incidence and prevalence of the different types of uveitis varies among regions of the world, depending on numerous factors: level of development, HLA distribution, prevalence of different infectious diseases in each region, and also the methodology employed by each physician to evaluate and classify uveitis (Table 73.3).¹⁰ Using a northern California database for enrollees in a health maintenance study, Gritz and Wong^{10a} recently reported an incidence of 52.4 per 100 000 per year and a prevalence of 115.3/100 000. Anterior uveitis is much more common than intermediate or posterior uveitis.

PREVENTION AND PATIENT MANAGEMENT

Uveitis can be the first sign of occult, potentially severe, systemic disease (for example sarcoidosis, syphilis, or central nervous system lymphoma). Despite the difficulty of successful systemic anti-inflammatory/ immunosuppressive treatment, there are some diagnoses that can be treated to complete recovery, such as syphilis. Therefore it is essential to identify as accurately as possible the cause of uveitis. A targeted approach is preferable, with a limited work-up guided by the type and severity of uveitis and the presence of systemic findings. The history assumes greater importance than in any other ophthalmic entity. The minimal work-up for uveitis of unknown etiology requires an extensive and careful review of systems, a syphilis serology, and a chest X-ray.¹¹

Most practitioners use a step-ladder approach to the treatment of uveitis. The first step is treatment with corticosteroids for all patients with noninfectious uveitis (topical, especially for anterior uveitis, local peribulbar injection, intravitreal injection, or systemic administration). A surgically implantable intravitreal device to release fluocinolone continuously for approximately 2.5 years is an additional option that is limited by cost and complications, which can include cataract, glaucoma, and scleral thinning.¹² Systemic immunosuppressive therapy should be used in cases of inadequate benefit from corticosteroids or unacceptable steroid side

Fig. 73.5 Posterior synechiae. The cloverleaf appearance of the pupil is due to the iris adhering to the lens.

Fig. 73.6 Band keratopathy. Calcium deposition in the corneal endothelium complicates the iridocyclitis in a patient with juvenile idiopathic arthritis.

effects. Immunosuppression is usually reserved for bilateral forms of uveitis with a severity sufficient to alter activities of daily living, and is frequently chosen for eye involvement with Behçet's disease. Immunosuppression may be contraindicated by active infection in the eye or elsewhere.

OVERVIEW OF THE MOST COMMON UVEITIS DIAGNOSES

Ankylosing spondylitis (AS) is the most common systemic diagnosis associated with uveitis in western nations. A genetic predisposition with the HLA-B27 marker is found in 88–96% of patients with AS. About 40% of AS patients develop anterior uveitis transiently during their

Fig. 73.7 Granulomatous keratic precipitates. Round white dots are scattered in a triangular shape. The dots represent concretions of leukocytes adherent to the corneal endothelium.

lifetime; conversely 30% of anterior uveitis patients have AS. Approximately 50% of patients with a sudden onset anterior uveitis are HLA-B27 positive. In some studies, 80–90% of individuals with HLA B27-associated iritis have a systemic disease, either ankylosing spondylitis or reactive arthritis. Ankylosing spondylitis should be considered in any patient with sudden onset, primarily anterior, unilateral uveitis associated with redness and pain. Recurrent disease, fibrin in the anterior chamber, posterior synechiae, relatively brief inflammation that resolves in less than 2 months, and lowered intraocular pressure are additional hallmarks that sometimes help to distinguish HLA-B27-associated iritis from other categories of intraocular inflammation.¹³ Cells can be seen in the anterior chamber by slit lamp examination. Inflammation is sometimes so severe that a hypopyon (Fig. 73.8) develops. The posterior segment of the eye is not commonly involved in this disease except for the development of a vision-reducing cystoid macular edema (see Figs 73.2, 73.4), which is a more frequent complication than with other forms of anterior uveitis. The disease usually shows a good response to topical corticosteroids. In frequently recurrent cases, therapy with sulfasalazine or TNF inhibitors has been shown to be effective in reducing the frequency and severity of the attacks.

Ocular manifestations of inflammatory bowel disease (IBD) (Crohn's disease and ulcerative colitis; Chapter 74) include iritis, episcleritis, and scleritis (1–9% of all cases). Twenty percent of patients with IBD may have sacroiliitis; 60% of these are HLA-B27 positive. The anterior uveitis in patients with IBD is often similar to that seen with the HLA-B27 spectrum of joint diseases (ankylosing spondylitis): sudden in onset, unilateral, and self-limited. But Crohn's disease is a granulomatous process: like sarcoidosis, it may result in intraocular inflammation that is insidious in onset, bilateral, posterior to the lens, chronic, or associated with a retinal vasculitis.¹⁴

Crohn's disease is a complex genetic disease, meaning that multiple genes undoubtedly contribute to susceptibility to this inflammation. One of the best-characterized of these genes is NOD-2, which is also known as CARD-15. This gene seems to function as an intracellular Toll

Table 73.2 Characteristic features of common forms of uveitis

Parameter	
Location	Anterior: Ankylosing spondylitis, reactive arthritis, juvenile idiopathic arthritis Intermediate: Pars planitis Posterior: Vogt–Koyanagi–Harada syndrome
Onset	Sudden: Ankylosing spondylitis, reactive arthritis Insidious: Pars planitis, juvenile idiopathic arthritis
Symmetry	Unilateral: Ankylosing spondylitis, toxoplasmosis Bilateral: Pars planitis, lymphoma, juvenile idiopathic arthritis
Course	Self-limited: Toxoplasmosis Recurrent: Behçet's disease, ankylosing spondylitis Chronic: Pars planitis

Table 73.3 Likelihood of developing uveitis in association with a specific disease

Diagnosis	Likelihood (%)
Ankylosing spondylitis	30
Sarcoidosis	25–50
Behçet's disease	80
Inflammatory bowel disease	1–9
Psoriatic arthritis	7
Juvenile idiopathic arthritis	<2–53
Multiple sclerosis	<1–2

receptor that recognizes muramyl dipeptide from both Gram-negative and Gram-positive bacteria. The NOD-2 gene has homology to genes implicated in autoinflammatory diseases such as familial cold urticaria. A mutation in the portion of the NOD-2 gene known as the nucleotide-binding domain results in a rare autosomal dominant form of uveitis known as Blau syndrome.

One percent of the population has psoriasis; 7% of psoriasis patients have arthritis; and 7% of patients with psoriasis and arthritis have uveitis. The diagnosis is made clinically with the typical findings of cutaneous changes (erythematous, hyperkeratotic rash) and joint disease. Patients with sacroiliac disease and psoriatic arthritis are especially likely to develop uveitis.

Ocular disease is the initial manifestation of sarcoidosis (Chapter 72) in 20% of patients. The systemic illness begins as ocular inflammation almost as often as it initially presents as pulmonary disease. Between 25% and 50% of patients with systemic sarcoidosis exhibit ocular inflammatory disease. In most case series sarcoidosis accounts for 3–10% of all patients with uveitis, and it therefore follows spondyloarthropathy as the second most common systemic illness associated with uveitis in North America and Europe. The diagnosis of sarcoidosis should always be considered in any patient presenting with a uveitis of unknown etiology.

**Fig. 73.8** Hypopyon. Intense inflammation has resulted in a creamy exudate (pus), seen as whitening over the inferior portion of the anterior chamber. In this example, hypopyon was secondary to rifabutin, not ankylosing spondylitis.

Sarcoidosis has a strong ethnic association: it occurs in the USA 10 times more frequently among African-Americans than among whites. Because it can affect almost every part of the eye, symptoms of ocular sarcoidosis vary widely depending on the distribution of pathology. Most commonly, patients will have a bilateral chronic granulomatous iridocyclitis.¹⁵ The disease often regresses clinically, with two-thirds of patients symptom-free after 10 years. Typical findings include 'mutton-fat' keratic precipitates of the cornea (Fig. 73.7), Koeppe and Busacca iris nodules, posterior synechiae (Fig. 73.5), and white clumps of cells ('snowballs') in the inferior anterior vitreous. A chest X-ray (or CT scan of the chest¹⁶) should be included in every basic work-up of patients with uveitis of unknown cause. The diagnosis is most reliably established by a biopsy that demonstrates the noncaseating granuloma in the absence of an infection or beryllium exposure. Possible biopsy sites include lymph nodes, lung, skin, oral mucosa, and conjunctiva. Serological abnormalities

Fig. 73.9 Fundus photograph showing retinal vasculitis. The scattered hemorrhages are secondary to the vasculitis. The patient has Behçet's syndrome.

are not sufficiently unique to establish a diagnosis. They include elevated serum angiotensin-converting enzyme and lysozyme levels. In general, the combination of uveitis and symmetrical hilar adenopathy is specific for sarcoidosis. It is therefore not necessary to obtain tissue confirmation when this presentation occurs. Topical, periocular, and systemic corticosteroids are the mainstay of therapy.

Behçet's syndrome is a generalized occlusive vasculitis of unknown cause (Chapter 58). It accounts for about 2.5% of patients at a North American referral uveitis clinic, and has a strong ethnic relationship. It is most common in Japan (20% of uveitis patients) and prevalent in Middle Eastern countries along the silk road.

The classic complex includes aphthous stomatitis, genital ulceration and iritis, sometimes with hypopyon (30% of patients), and skin lesions. The posterior segment is more commonly involved than the anterior and includes an occlusive retinal vasculitis (Fig. 73.9).¹⁷ Extraocular manifestations most commonly include arthritis, erythema nodosum, diarrhea (mimicking inflammatory bowel disease), and sterile meningitis. There is a strong tendency for the symptoms to remit and exacerbate spontaneously. HLA-B5 or its subset, B51, is more commonly found among Behçet's patients. Behçet's syndrome may lead to blindness if ischemic optic neuropathy and retinopathy are not adequately treated. Patients are often inadequately managed by corticosteroids alone: a regimen with immunosuppressive drugs (cyclosporine A) or azathioprine has been proved useful. Some investigators advocate the use of α -interferon.¹⁸ Infliximab has demonstrated dramatic benefit in studies reported from Europe and Japan.¹⁹

Although retrobulbar optic neuritis is the ocular inflammation most clearly associated with multiple sclerosis, both intermediate uveitis (pars planitis) and a bilateral granulomatous anterior uveitis are well described in association with this demyelinating central nervous system disease²⁰ (Chapter 65). The granulomatous inflammation is typically bilateral and may indicate a worse prognosis for the neurologic disease. The HLA-DR2 antigen, strongly associated with MS, is also associated with uveitis.

Patients with juvenile idiopathic arthritis (JIA; Chapter 53) need special consideration as the disease often does not present with a 'red eye:' the

uveitis is often a smoldering, silent inflammation with a quiet, white eye. These young patients need to be screened on a routine basis to avoid structural damage to the eye from even low-grade inflammation with resulting blindness. In 20% of all JIA cases the joint involvement is pauciarticular (five or fewer joints affected). Uveitis occurs far more commonly in this pauciarticular subset, and these patients require ophthalmic screening every 3–4 months. Girls are affected four times more often than boys, although boys may be more likely to develop complications.²¹ Eighty percent of uveitis cases are positive for anti-nuclear antibodies (ANA) and negative for rheumatoid factor. The onset of ocular disease is usually within 5 years of arthritis. Biomicroscopically, bilateral fine keratic precipitates, band keratopathy (Fig. 73.4), flare and cells in the anterior chamber, posterior synechiae, glaucoma and cataract formation can be found. Topical and periocular corticosteroid treatment with a slow taper is the mainstay of therapy. Systemic therapy with methotrexate can be used as a substitute for corticosteroids in selected cases. Cataract surgery is a special challenge and may require intense perioperative immunosuppression.

KEY CONCEPT

Immune-mediated diseases can affect virtually any portion of the eye. Uveitis, scleritis, keratoconjunctivitis sicca, conjunctivitis, optic neuritis, keratitis, and orbital pseudotumor are examples of eye diseases that are frequently immune mediated.

CLINICAL PEARL

The immune privilege of the eye does not prevent immune-mediated eye disease.

SCLERITIS

DESCRIPTION/NATURAL HISTORY

Scleritis is a relatively uncommon inflammation that affects the sclera, the white tunic that encases the posterior eye. Scleritis is usually presumed to represent a vasculitis of scleral vessels. Approximately 50% of patients with scleritis will have clinical evidence for a systemic vasculitis elsewhere in the body. The most common systemic disease is rheumatoid arthritis (RA; Chapter 52), especially the subset of patients with rheumatoid nodules, high-titer rheumatoid factor, and pleuropericarditis as well as small vessel vasculitis of the lower extremities. Other systemic diseases commonly associated with scleritis are listed in Table 73.4. The epidemiology of scleritis has not been adequately reported. However, rheumatoid arthritis accounts for about one-third of all cases of scleritis. Because only 1% of patients with rheumatoid arthritis develop scleritis and about 1% of the population has RA one can estimate that the prevalence of scleritis is $0.01 \times 0.01 \times 3$, or 3/10 000.

Scleritis is frequently divided into five subsets based on the clinical presentation: diffuse anterior (Fig. 73.10); nodular anterior; necrotizing; scleromalacia perforans (Fig. 73.11); and posterior. Scleromalacia perforans is also known as necrotizing without inflammation. The clinical presentation will vary according to the type, but scleritis is usually a very painful and persistent condition. Even with treatment, a median duration reaches 7 years.

Table 73.4 Systemic immune-mediated diseases associated with scleritis

Ankylosing spondylitis
Relapsing polychondritis
Rheumatic fever
IgA nephropathy

Fig. 73.10 Diffuse anterior scleritis. The red patch of vessels temporally is secondary to scleritis.

GENETIC/ENVIRONMENTAL FACTORS

Genetic factors affecting scleritis have not been adequately studied. Genes that affect the associated systemic diseases, such as RA, Wegener's granulomatosis, and polyarteritis, presumably also influence susceptibility to scleritis. Environmental triggers for scleritis have not been defined, except that some cases of scleritis can be a manifestation of infection, such as herpes zoster ophthalmicus, syphilis, or Lyme disease, as well as other bacterial and fungal infections.

IMMUNOLOGY/PATHOLOGY

Biopsy of the sclera entails some risk. Accordingly, many of the published histological observations are based on end-stage or extremely severe disease. In one pathology study of 55 examples of necrotizing scleritis the histology was divided into four types: zonal necrotizing granulomatous; nonzonal diffuse; necrotizing with microabscess; and sarcoidal granulomatous.²² Eighty-five percent of patients with zonal necrotizing granulomatous pathology had a systemic disease, usually rheumatoid arthritis.

Fig. 73.11 Scleromalacia perforans. Blue sclera is visible secondary to inflammation, resembling a rheumatoid nodule in the eye.

The pathology associated with RA was not distinct from other systemic diseases such as Wegener's granulomatosis. None of 19 patients with nonzonal diffuse scleral inflammation had a systemic disease. Just over half of the patients with microabscesses had an identifiable infection as the cause of scleritis. Only one patient had 'sarcoidal granulomatous inflammation,' and that patient had sarcoidosis.

PREVENTION/MANAGEMENT

Topical medications are only slightly beneficial for most patients with scleritis. Topical nonsteroidal anti-inflammatory drugs (NSAIDs), such as ketorolac, have not been proved efficacious in a controlled study. A topical corticosteroid can sometimes help in symptomatic control but also has risk, especially the promotion of cataract formation and elevation of intraocular pressure. The role for topical cyclosporine has not been adequately evaluated, but the authors' clinical experience has not been favorable.

Although most forms of scleritis represent a vasculitis, oral NSAIDs can be immensely beneficial. Although not all patients derive adequate control from NSAIDs, a subset will benefit sufficiently such that no other medication is required. Indomethacin has most frequently been reported to be effective,²³ but other NSAIDs have simply not been tested in a sufficiently large sample population. A recent report demonstrates that celecoxib is an effective option.

Many patients with scleritis will not benefit adequately from a nonsteroidal agent and will require immunosuppression. In general, for those with an associated systemic disease the control of that disease will lead to control of the scleritis. For those without a systemic illness, oral corticosteroids are an accepted initial approach to treatment. For example, therapy might begin with a dose of prednisone of 1 mg/kg bodyweight per day. The use of calcium and vitamin D, and other measures to preserve bone mineral density, should be considered for any patient who will be receiving corticosteroid on a chronic basis. If prednisone is not adequate for disease control, or if the medication is toxic, poorly tolerated, and cannot be safely tapered to a modest dosage, it is reasonable to add a steroid-sparing

medication such as methotrexate, azathioprine, cyclosporine, mycophenolate, or even an alkylating agent such as cyclophosphamide.

Periocular corticosteroids are very effective for uveitis, but they are relatively contraindicated for patients with necrotizing scleritis. The steroid probably promotes reduced wound healing and thus enhances the likelihood that the sclera might perforate as a result of the inflammation. Scleral inflammation limited to the posterior sclera can probably be safely treated with a periocular steroid injection. Anterior scleritis that is nonnecrotizing also responds to the cautious use of periocular corticosteroid injection.

In choosing to treat with oral corticosteroid or an immunosuppressive, the clinician will, of course, weigh the risk/benefit ratio. The rationale for aggressive therapy is much stronger if the disease is bilateral and is affecting activities of daily living, because of either pain or a reduction in visual acuity.

CLINICAL PEARLS

Uveitis and scleritis are frequently associated with a systemic illness. These illnesses can usually be diagnosed by history without resorting to extensive laboratory testing.

EVALUATION/DIFFERENTIAL DIAGNOSIS

Patients with scleritis generally have characteristic findings that allow an accurate diagnosis; scleritis can usually be readily distinguished from other causes of a red, painful eye. The most difficult distinction is between scleritis and episcleritis. The episclera overlies the sclera. In general patients with episcleritis do not experience pain, do not have an associated systemic disease, do not have complications such as iritis or glaucoma, and have an excellent prognosis, with complete resolution usually within weeks. The differences between scleritis and episcleritis are highlighted in Table 73.5.

The scleritis associated with a systemic vasculitis is often more severe than scleritis not associated with a systemic illness.²⁴ The scleritis associated with Wegener's granulomatosis may be particularly destructive and refractory to therapy.²⁵ Scleritis in association with rheumatoid arthritis is often a poor prognostic sign for the joint disease. For example, the small subset of patients with scleritis in association with rheumatoid arthritis have a shortened life expectancy compared to other patients with RA and no evidence for scleritis.

Posterior scleritis can be an extremely difficult disease to diagnose. If the anterior sclera is uninvolved, no redness is present. Pain with posterior scleritis is much more variable. The examination may show elevation of the adjacent retina and choroid. The diagnosis can be confirmed with an ultrasound examination or, less commonly, with a CT scan of the orbit demonstrating thickening of the sclera. Posterior scleritis is treated similarly to anterior scleritis, except that topical corticosteroids are not useful and a periocular corticosteroid injection can be given safely.

PITFALLS/CONTROVERSY

Some experts believe that scleritis is often a forme fruste of Wegener's granulomatosis. It clearly occurs in association with Wegener's granulomatosis, and patients with scleritis, a positive ANCA test, and no other evidence for Wegener's granulomatosis have been well described.²⁶

With the exception of the ANCA, laboratory studies are generally selected according to the history and general physical examination. For example, although rheumatoid arthritis is associated with scleritis, the patients almost always have long-standing severe RA. A rheumatoid factor would not be an appropriate test if no joint disease were present clinically. Similarly, systemic lupus can be associated with scleritis, but one would not diagnose lupus on the basis of a positive ANA, scleritis, and the absence of other findings to suggest lupus. An erythrocyte sedimentation rate can sometimes be helpful in reassuring that a systemic process is not present. Other laboratory tests are largely dictated by the medication that is chosen and how that medication is monitored.

KERATITIS

The cornea is the anteriorly situated window to the eye. Normally it should be clear. It can become opacified due to trauma, exposure to toxins, infection, dryness, calcium deposition, or genetic diseases such as corneal dystrophies. The three main immune-mediated diseases that affect the cornea are corneal melt, Mooren's ulcer, and Cogan's syndrome.

Corneal melt is also known as marginal keratolysis (Fig. 73.12). The majority of patients have an associated systemic form of vasculitis and usually scleritis. The medical therapy is basically the same as that described for scleritis, with emphasis on controlling the underlying systemic illness and the use of immunosuppression. Corneal melt often leads to perforation of the eye. This is usually treated surgically with tissue adhesives, conjunctival flaps, or corneal transplantation, in addition to aggressive systemic

Table 73.5 Contrasting features of scleritis and episcleritis

	Scleritis	Episcleritis
Pain	Prominent	Minimal
Duration	Years	Days to several months
Association with systemic disease	Frequent	Rare
Vessels blanch with topical vasoconstrictor	No	Yes
Associated ocular complications including visual loss	Sometimes present	Never
Vessel color	Deep pink to violaceous	Light pink

Fig. 73.12 Corneal melt. A pie-shaped wedge of the cornea is thinned. The eye is red secondary to an associated scleritis.

immunosuppression. Corneal melt is fortunately a very rare disease. A melt must also be distinguished from some other causes of corneal thinning, such as Terrien's marginal degeneration or a senile marginal furrow, both of which are generally more benign and rarely lead to perforation.

Mooren's ulcer is clinically very similar to a melt, except that there is no accompanying scleritis and no evidence for a systemic illness. The superior cornea is especially likely to be involved. Mooren's ulcer is too rare for therapeutic options to be studied with randomized clinical trials. It may respond to oral immunosuppression, which is warranted if the severity threatens visual acuity because of impending perforation of the eye. A small study not confirmed by subsequent investigation suggested that Mooren's ulcer is frequently associated with evidence of previous infection with hepatitis C.²⁷ Some patients with Mooren's ulcer have an autoantibody to calgranulin C. This antigen is expressed in cornea, in neutrophils, and by filarial nematodes.

The cornea is divided into three layers: the epithelium facing the atmosphere, the stroma, and the endothelium abutting the aqueous humor. Opacification of the stroma is known as interstitial keratitis. Congenital syphilis and other infections such as herpes simplex are important causes of this. Cogan's syndrome is defined as an autoimmune disease of the eighth nerve combined with interstitial keratitis, presumably also on an autoimmune basis.²⁸ Some ophthalmologists also recognize autoimmune eighth-nerve disease associated with other forms of ocular inflammation, such as uveitis, as examples of Cogan's disease.²⁹ The pathogenesis of Cogan's syndrome is presumed to be a vasculitis, and many patients will have evidence for vasculitis elsewhere in the body. The treatment usually requires aggressive use of systemic immunosuppressive medications.

CORNEAL TRANSPLANTATION AND TRANSPLANT REJECTION

Corneal transplantation involves the replacement of a diseased cornea with healthy cadaver tissue. Since the 1970s, advances in microsurgical techniques and eye banking procedures have lead to widespread acceptance of

this procedure. Currently corneal transplantation is performed 40 000 times annually in the USA alone. The usual indication for a corneal graft is poor vision, although the operation may also be undertaken to relieve ocular pain. Keratoconus, a condition in which myopic astigmatism develops as the cornea becomes progressively more conical in shape, corneal edema following intraocular surgery, and a failed previous corneal graft are the commonest medical conditions leading to corneal transplantation.³⁰

Although the eye is an immune privileged site, and corneal transplants enjoy a 91% 1-year survival as shown by Kaplan-Meier survival analyses, only 62% of grafts are functional at 10 years.³⁰ The commonest cause of transplant failure is immunological rejection.³⁰ Corneal allograft rejection rarely occurs within 2 weeks, and may occur as late as 20 years following surgery. Animal studies using monoclonal antibodies directed against different T-cell subsets indicate that CD4 T cells play a critical role in the rejection response. However, the exact mechanisms responsible for this process are yet to be elucidated.

Early recognition of a rejection episode is the most important factor in achieving survival of the corneal transplant. In its most florid form, the anterior eye is obviously inflamed, with intense conjunctival injection, a cellular anterior chamber reaction and a Khodadoust line. This line, which is visible with the slit-lamp biomicroscope, is a classic sign of corneal graft rejection. It appears as a linear formation of inflammatory precipitates stretching across the corneal endothelium and represents a wave of lymphocytes marching across the cornea and destroying the endothelium in their path.³¹ As endothelial pump function is lost, the cornea becomes waterlogged and opaque. At an early stage of rejection the patient may be asymptomatic, but later, ocular redness, photophobia, halos and blurred vision are frequent complaints.

An intensive and extended course of topical corticosteroids is the mainstay of treatment for a rejecting corneal graft, and in severe cases intravenous and/or oral corticosteroids may also be administered. Patients considered to be at high risk of transplant rejection, such as those with corneal neovascularization or a history of other anterior segment inflammation, are often given perioperative systemic immunosuppression. The ideal prophylactic regimen has not been defined, although various combinations of prednisone, cyclosporine and azathioprine may be used. Despite the critical influence of donor-recipient histocompatibility matching for solid organ transplant survival, the chance of corneal graft survival is not significantly improved by HLA matching.

CANCER-ASSOCIATED RETINOPATHY

Cancer-associated retinopathy (CAR) is a rare paraneoplastic syndrome that is most commonly induced by small cell carcinoma of the lung.³² In addition, the disease has been documented in association with various tumors of the female reproductive tract, carcinoma of the breast and neuroendocrine bronchial carcinoma. For 50% of patients CAR is the presenting feature of their malignancy. Interestingly, there are now reports of retinopathy mimicking CAR, but occurring in an apparently healthy individual. Melanoma-associated retinopathy is a related syndrome, occurring in patients with metastatic cutaneous melanoma.

Histopathological examinations of postmortem specimens taken from patients with CAR consistently demonstrate loss of inner and outer segments of the retinal photoreceptors. This destruction was initially attributed to the release of a hormone-like substance by the malignant cells,

but evidence has now accumulated in support of an autoimmune etiology. Affected individuals produce antibodies against one or more retinal photoreceptor antigens.³³ These antibodies induce experimental CAR when injected into laboratory animals. Although over 15 antigens have been described in relation to CAR, the commonest is the so-called CAR antigen.³³ This 23-kDa protein has been identified as recoverin, a photoreceptor protein that participates in visual adaptation. Experimental work supports the hypothesis that a single mutational event simultaneously activates the recoverin gene and eliminates functional p53, a tumor suppressor protein.³⁴ Consequently, there is development of a tumor that encodes for CAR antigen and stimulates formation of anti-recoverin antibody. Anti-recoverin antibodies are capable of inducing photoreceptor apoptosis, leading to the characteristic loss of both rods and cones.

Cancer-associated retinopathy generally occurs after the age of 60. Patients usually complain of decreased vision, although other symptoms may include transient visual obscurations, various positive visual phenomena, night blindness, scotomata, glare and photosensitivity. Although visual acuity may be dramatically reduced, other clinical signs are often subtle. Color vision can be impaired. An afferent pupillary defect can be present if the retinopathy is asymmetric. There may be mild iridocyclitis and/or vitritis, narrowing of retinal arterioles, mottling of retinal pigment epithelium and optic disc pallor. Visual field abnormalities occur, the most common being several midperipheral scotomata that later join up as a ring scotoma or central defect. Electroretinography shows either reduced or completely flattened amplitudes. The disease must be differentiated from optic neuritis which, unlike CAR, typically occurs in younger persons, some of whom suffer from multiple sclerosis, and is painful. In contrast to CAR, optic neuritis typically has an abrupt onset. In patients with malignancy, direct tumor spread and the effects of drugs, including chemotherapy agents, must be excluded before CAR is diagnosed.

The natural history of CAR is one of progressive visual loss, although this occurs over a variable period. Treatment directed towards curing or palliating the malignancy does not appear to prevent this loss. A series of case reports have documented improvement of vision in response to systemic corticosteroid therapy. High doses (60–80 mg) of prednisone have been used, but the minimum dose for preservation of vision is uncertain. Corticosteroid-sparing systemic immunosuppression has also been used to treat this disease. It is suggested that monitoring serum antibody levels can be used to guide therapy. However, in some cases advanced photoreceptor damage may be irreversible despite therapy.

■ IMMUNOLOGIC ETIOLOGICAL FACTORS IN 'NONIMMUNOLOGIC' OCULAR DISEASE ■

The eye contains many unique proteins that are sequestered from the immune system in early development, and which, if released systemically during adulthood, could act as autoantigens. Autoantibodies directed against certain ocular proteins have been detected in the serum of patients with a variety of ocular diseases traditionally regarded as non-immunologic. Examples of such conditions include cataract, glaucoma, age-related macular degeneration (AMD), and retinal degenerative diseases such as retinitis pigmentosa (RP). The unanswered question is whether these antibodies contribute to the pathogenesis of the disease or merely coexist as an epiphenomenon.

Cataract is an opacification of the crystalline lens of the eye. It is the most frequent cause of blindness worldwide, most commonly occurring as an age-related phenomenon. The prevalence of cataract is approximately 70% in those over 75 years of age. The pathogenesis is poorly understood, and many varied mechanisms, including autoimmunity, have been hypothesized. Autoantibodies to sequestered lens proteins termed crystallins are present in some normal individuals, but occur significantly more frequently in patients with cataract. Immune complexes have been demonstrated in human cataractous lenses. Immunization of rabbits with human lens protein can induce cataract formation which is suppressed by systemic corticosteroid therapy. Human sera containing autoantibodies against lens proteins are cytotoxic for lens epithelial cells in culture.³⁵ On the other hand, it has not been possible to demonstrate T cell-mediated immune responses to lens proteins experimentally, suggesting that a process of active tolerance might prevent these autoantigens from inducing significant inflammation.

In glaucoma, a relative elevation of intraocular pressure is associated with optic nerve damage and visual field loss. More than 3 million people in the world are irreversibly blind owing to this disease, the basic mechanisms of which continue to puzzle clinicians and scientists despite very extensive research. There is recent evidence that autoimmunity may play a role in glaucoma, at least for a subgroup of affected individuals with so-called normal-tension glaucoma, in which there is no apparent elevation in intraocular pressure above population normal levels. Increased titers of various autoantibodies, including antibodies directed against extractable nuclear antigens, retinal heat shock proteins, and the retinal photoreceptor protein rhodopsin, have been measured in patients with normal-tension glaucoma. In addition, autoantibodies to optic nerve head glycosaminoglycans have been detected in the serum and optic nerve of patients with glaucoma, including the normal-tension form. It is postulated that these anti-glycosaminoglycan antibodies may increase the susceptibility of the optic nerve head to glaucomatous disease by altering physical characteristics of the tissue.

Age-related macular degeneration is the leading cause of irreversible visual loss for elderly persons in western nations. A spectrum of pathologies may occur at the macula, ranging from relatively benign focal hypo- and hyperpigmentation of the retinal pigment epithelium to sinister subretinal neovascularizations which may leak serous fluid and blood. The pathogenic stimulus for these aging changes is unknown. Genetic polymorphism of the complement regulatory protein, complement factor H, influences the susceptibility to AMD, suggesting that this disease is related to chronic inflammation.³⁶ Subretinal scar tissue removed from patients with advanced disease may contain immunoglobulins and complement components. The histopathology of AMD includes a few inflammatory cells, including lymphocyte subsets, and local cell populations may express class II MHC antigens. A mouse model of retinal changes that resemble macular degeneration is associated with the deletion of a receptor for a chemotactic factor for macrophages.³⁷ Macular drusen, seen early in the course of AMD, may also contain immunoglobulin.

Retinitis pigmentosa is a hereditary pigmentary degeneration of the retina. Just under half of patients have no family history. Various anti-retinal antibodies have been detected in approximately half of patients with this disease, including antibodies directed against the enzymes carbonic anhydrase II and enolase.³⁸ Interestingly, there is a significant association between the occurrence of cystoid edema at the macula, a dreaded vision-threatening complication of RP, and the presence of the

circulating anti-retinal antibodies. The complication has been reported in 90% of affected individuals with antibodies, compared to only 13% of patients who are antibody negative. A less convincing association is that between an accelerated rate of visual field loss and the presence of anti-retinal antibodies.³⁸

Immunologic disease of the gastrointestinal tract

Charles O. Elson III, Phillip D. Smith

74

The gastrointestinal tract mucosa is a major immune system organ, contains the majority of lymphocytes and produces the majority of immunoglobulins synthesized in the body. The host immune system interacts with the microbiota and with foreign antigens in food most directly and intimately in the intestine. It is therefore not surprising that the intestine is affected by a variety of immunodeficiencies, by chronic infections of the mucosa, and by autoimmune and idiopathic chronic inflammatory diseases. This chapter describes the spectrum of different immune disorders involving the gastrointestinal tract.

■ GASTROINTESTINAL DISORDERS ASSOCIATED WITH PRIMARY IMMUNODEFICIENCY ■

Primary immunodeficiency diseases are uncommon disorders caused by congenital defects in B, T, or phagocytic cells. These diseases are frequently associated with an array of gastrointestinal illnesses that vary in severity, depending on the type of underlying immunodeficiency, the level of immune dysfunction, and the presence of enteric pathogens.¹ Importantly, the association between gastrointestinal illnesses and immunodeficiency disease emphasizes the fundamental role of systemic and mucosal immunity in maintaining gastrointestinal health. Here we describe the major immunodeficiency diseases and their associated gastrointestinal manifestations.

COMMON VARIABLE IMMUNODEFICIENCY DISEASE

Diagnosis

Common variable immunodeficiency (CVID) is an uncommon disorder (1 in 50 000 Caucasians) characterized by reduced concentrations of most or all immunoglobulin (Ig) isotypes (IgG, IgA, IgE and IgM) with defective specific-antibody production; frequent sinopulmonary and gastrointestinal

infections; and less frequent immunologic abnormalities, including autoimmune and lymphoproliferative disorders (Chapter 34).² CVID occurs equally in men and women and typically presents in the third decade of life, with a small subset presenting in early childhood. The late presentation of CVID suggests an acquired disease, but a familial association of individuals with CVID is consistent with an inherited disorder.

Individuals with CVID usually have normal numbers of surface Ig-bearing B-cell precursors, but the cells are unable to differentiate into Ig-secreting cells. This defect is accompanied by variable reductions in the secretion of IgA and IgG in most patients, as well as IgM and IgE in many, resulting in corresponding reductions in serum Ig levels and defective antigen-specific antibody responses. Cell-mediated immunity is usually normal in CVID, although a subset of patients display T-cell abnormalities, including impaired T-cell receptor and CD28 signaling, reduced expression of activation molecules, reduced Th2 cytokine secretion, enhanced apoptosis, and deficient inducible co-stimulator molecule expression.³ These abnormalities lead to a reduction in T-cell activation and proliferation. The role of T cells in regulating B-cell function was demonstrated indirectly by the normalization of reduced Ig levels and impaired antibody responses in a patient with CVID after he acquired HIV-1 infection and depleted his T cells, allowing restoration of B-cell function.⁴ Defective myeloid dendritic cell function has also been reported in some patients with CVID.⁵

Clinical manifestations

As a consequence of the above immune defects, patients with CVID have a high incidence of sinopulmonary infections and gastrointestinal manifestations. Recurrent pulmonary infection can lead to irreversible chronic lung disease with bronchiectasis. The most common pathogens include the encapsulated bacteria *Streptococcus pneumoniae* and *Hemophilus influenzae*. In normal persons, IgG antibodies, particularly of the IgG₂ subclass, are directed against encapsulated bacteria and are the major opsinin in mucosal fluids; among patients with CVID, those with IgG₂ deficiency have the highest frequency of infections with encapsulated bacteria.

Among the gastrointestinal manifestations of CVID, chronic diarrhea is the most common. In population-based studies, the protozoan parasite *Giardia lamblia* has been identified in up to 90% of CVID patients with diarrhea and in 10% of those without.⁶ Infections with *Campylobacter jejuni* and *Salmonella* spp. and bacterial overgrowth are also the cause of recurrent diarrheal illness in patients with CVID. Among children with CVID, *Clostridium difficile* and rotavirus are also noted causes of diarrheal illness. Noninfectious gastrointestinal manifestations of CVID include atrophic gastritis with achlorhydria, which in some patients may progress to pernicious anemia in the absence of anti-parietal cell antibodies. A subset of patients develops a sprue-like enteritis characterized by partial villous atrophy, malabsorption and persistent diarrhea. In contrast to classic celiac disease, the sprue-like enteritis associated with CVID does not respond to gluten restriction. Rarely, diarrhea and malabsorption may occur in the presence of normal intestinal mucosa, possibly owing to increased numbers of intestinal bacteria in association with achlorhydria. Other noninfectious gastrointestinal manifestations of CVID include nodular lymphoid hyperplasia of the intestine (but not the colon), aphthous stomatitis, autoimmune hepatitis, and primary biliary cirrhosis.⁷ Colonic inflammation ranging from microscopic colitis to inflammatory bowel disease-like colitis has been reported in CVID.⁸ Nongastrointestinal autoimmune disorders also have been reported in CVID, including Graves' disease, hypothyroidism, rheumatoid arthritis, systemic lupus erythematosus, and Sjögren's syndrome. CVID is associated with an increased incidence of certain malignancies, including intestinal lymphomas with a B-cell phenotype and gastric adenocarcinoma (increased 50-fold).

Treatment

Mainstays of the management of CVID are antimicrobial therapy, immunoglobulin replacement, and surveillance for recurrent infections, autoimmune disorders and malignancies. Antibiotic therapy should be pathogen specific and may require prolonged intravenous administration. The frequency of infections is reduced with intravenous Ig (IVIG) therapy. The dosage and frequency of IVIG administration should be individualized, depending on the incidence and severity of infections. Fat-soluble vitamins and supportive treatment are indicated in patients with malabsorption.

KEY CONCEPTS

GASTROINTESTINAL PROCESSES ASSOCIATED WITH COMMON VARIABLE IMMUNOGLOBULIN DEFICIENCY

- >> Infections: *G. lamblia* (common), *C. jejuni* and *Salmonella* sp. (less common);
- >> *C. difficile* and rotavirus (children); bacterial overgrowth
- >> Sprue-like enteritis unresponsive to gluten-restriction
- >> Nodular lymphoid hyperplasia (intestine)
- >> Aphthous stomatitis
- >> Hepatic disorders: Autoimmune hepatitis and primary biliary cirrhosis
- >> Inflammatory bowel disease-like colitis

SELECTIVE IgA DEFICIENCY

Diagnosis

Selective IgA deficiency (IgAD) is the most common primary immunodeficiency disease, affecting approximately 1 in 700 persons (Chapter 34). Most patients with IgAD have undetectable serum IgA with normal (or elevated) levels of other Igs and normal cell-mediated immunity. A subset of patients have partial IgA deficiency, with IgA levels more than two standard deviations below the mean serum level for their age. Like CVID, IgAD is considerably less common in persons of African descent. A subset of patients has elevated IgE levels. Although B-cell maturation is arrested at an early stage in IgAD, the mechanism underlying this defect is not known.

Clinical manifestations

The most common clinical presentation of IgAD is recurrent upper respiratory tract infections, usually beginning in childhood. However, the majority of patients with IgAD are asymptomatic; consequently, a diagnosis of IgAD does not predict severe life-threatening illness. After recurrent respiratory infections, autoimmune disorders, asthma, and allergic conditions are the most common problems associated with IgAD. The autoimmune disorders are similar to those in patients with CVID. The allergic conditions include allergic rhinitis, conjunctivitis, urticaria and atopic eczema, which are more common in IgAD patients with increased levels of IgE. Regarding gastrointestinal complications, intestinal infections are not more common than in the general population. In particular, *G. lamblia* infection is not more common in persons with IgAD; rather, it is more common in patients with CVID. However, patients with IgAD have an array of noninfectious gastrointestinal complications, including celiac sprue associated with malabsorption and responsive to gluten restriction; pernicious anemia; disaccharidase deficiencies such as lactase deficiency; and pancreatic insufficiency. Gastric and colonic adenocarcinoma appears to be more common in IgAD. Hepatobiliary manifestations include chronic active hepatitis, lupoid hepatitis, primary biliary cirrhosis, and cholelithiasis.

Treatment

Currently available preparations of γ -globulin do not contain sufficient amounts of IgA to warrant replacement therapy, nor is there evidence that parenterally administered Ig is secreted at mucosal surfaces. Rather, therapy in patients with IgAD is directed to the specific complication. Treatment of sinopulmonary infections should be pathogen specific, although chronic sinusitis may require prolonged broad-spectrum

CLINICAL PEARLS

- >> *G. lamblia* infection is associated with CVID disease, not selective IgA deficiency.
- >> Sprue-like enteritis unresponsive to gluten is associated with CVID, but sprue-like enteritis responsive to gluten is associated with IgA deficiency.

antibiotic therapy. Autoimmune and allergic conditions are treated as they would be in patients without IgAD. Because patients with IgAD may have IgG or IgE antibodies to IgA, serious reactions may be elicited by blood transfusion.

X-LINKED AGAMMAGLOBULINEMIA

Diagnosis

X-linked agammaglobulinemia (XLA, also known as congenital or Bruton's agammaglobulinemia) is a rare B-cell disease associated with dysfunction of the gene encoding Bruton's tyrosine kinase (BTK), which is present on the X chromosome at position Xq22 (Chapter 34). *BTK* dysfunction leads to B-cell maturation arrest, a near total absence of mature B cells, and agammaglobulinemia. T-cell numbers and function are normal.

Clinical manifestations

XLA typically manifests during infancy or early childhood with recurrent sinopulmonary infections due to encapsulated bacteria, resembling CVID. Gastrointestinal complications are less frequent than in other Ig deficiency diseases. *G. lamblia* infection is common in XLA, and *Campylobacter* infections also have been detected, albeit less frequently. Perirectal abscess and small bowel bacterial overgrowth have been described in XLA, but are uncommon. Importantly, children with XLA may suffer from devastating systemic manifestations of chronic enteroviral infections. The latter include paralytic polio infections following either natural infection or oral immunization with live vaccine and enteroviral meningoencephalitis and arthritis. Opportunistic pathogens are uncommon due to normal T-cell function.

Treatment

Sinopulmonary hygiene and pathogen-specific antimicrobial therapy are central to the management of XLA. In addition, IVIG replacement therapy should be initiated as early as possible to limit recurrent infections and prevent infection-induced bronchiectasis. Perirectal abscess usually requires surgical intervention in addition to antibiotic therapy.

CHRONIC GRANULOMATOUS DISEASE

Diagnosis

Chronic granulomatous disease (CGD) is a group of four inherited disorders characterized by severe bacterial and fungal infections and the formation of granulomas in the gastrointestinal and urinary tracts (Chapter 21). CGD is rare, occurring in 0.5–1 per 100 000 persons, and is usually inherited in an X-linked recessive pattern, but autosomal recessive inheritance may occur in up to 40% of patients.

Clinical manifestations

Patients with CGD present in infancy or early childhood having severe infections with catalase-positive pathogens and inflammatory granulomas. The most common pathogen is *Staphylococcus aureus*,

followed by *Burkholderia cepacia* and *B. gladioli*, *Serratia marcescens*, *Chromobacterium violaceum*, *Aspergillus* sp. and *Nocardia* sp. The infections manifest as pneumonia, liver abscess (up to 55% of patients), perianal abscess, skin abscess, lymphadenitis and osteomyelitis. Although inflammatory granulomas may occur in virtually any organ, they typically involve the gastrointestinal and urinary tracts, leading to pyloric, bladder and ureteral obstruction. Granulomas in the gastrointestinal mucosa have been associated with diarrhea and malabsorption, including steatorrhea.

Treatment

Prophylactic antimicrobial therapy reduces the incidence of bacterial and probably also fungal infections in patients with CGD. Prophylactic administration of subcutaneous interferon- γ has also been shown to reduce the number and severity of infections. Once an infection has developed, antibiotic therapy is directed to the specific pathogen. Hepatic abscess, most commonly due to *S. aureus*, occurs in approximately 30% of patients, may be recurrent, and requires surgical treatment. Granulomas that produce obstruction and/or significant symptoms respond to corticosteroid therapy.

SEVERE COMBINED IMMUNODEFICIENCY DISEASE

Diagnosis

Severe combined immunodeficiency disease (SCID) is a group of inherited disorders characterized by profound defects in T-cell and usually B-cell maturation and function (Chapter 35). The pattern of inheritance is X-linked recessive or autosomal recessive, with an incidence of 1/50 000–1/100 000 persons.

Clinical manifestation

Patients with SCID present in the first few months of life with severe infections, usually of the lung and gastrointestinal tract. Oral candidiasis, chronic diarrhea with malabsorption, and interstitial pneumonitis lead to malnutrition and growth impairment. Common pathogens include opportunistic agents such as *Pneumocystis jiroveci* and *Aspergillus* sp., intracellular bacteria such as *Listeria monocytogenes* and *Legionella pneumophila*, and viruses such as herpes viruses and Epstein-Barr virus. Graft-versus-host disease (GVHD) caused by transplacentally acquired maternal lymphocytes may cause life-threatening disease. Gastrointestinal infection with cytomegalovirus and rotavirus may cause persistent diarrhea and malabsorption. Diarrhea associated with partial villous atrophy and periodic acid-Schiff-positive mucosal macrophages may be present, exacerbating the failure to thrive.

Treatment

In the absence of bone marrow transplantation SCID is fatal. Live vaccines should not be administered because they can cause life-threatening infections. Infections should be treated as described for other immunodeficiencies. Blood products are irradiated prior to transfusion to prevent fatal GVHD.

■ GASTROINTESTINAL DISEASES THAT CAUSE IMMUNODEFICIENCY ■

Protein-losing enteropathy due to gastrointestinal and extra-intestinal disease can lead to excessive loss of proteins, including serum Igs. Causes of protein-losing enteropathy include increased interstitial pressure (intestinal lymphangiectasia, mesenteric lymphatic obstruction, tuberculosis, sarcoidosis, lymphoma, retroperitoneal fibrosis or constrictive pericarditis and congestive heart failure), ulcerative gastric or intestinal/colonic disease (Crohn's disease, pseudomembranous colitis or graft-versus-host disease) and nonulcerative diseases (Ménétriér's disease, infectious enteropathies, Whipple's disease, eosinophilic gastroenteritis and sprue). Here we discuss intestinal lymphangiectasia and Whipple's disease, two prototype intestinal diseases that can lead to immunodeficiency.

INTESTINAL LYMPHANGIECTASIA

Diagnosis

Intestinal lymphangiectasia (IL) is a rare disease that occurs as a primary congenital disorder (Milroy's disease) or as a secondary disorder due to the causes of increased interstitial pressure listed above. Increased intestinal lymphatic pressure leads to intestinal leakage of lymph, impaired absorption of chylomicrons, and reduced re-entry of intestinal lymphocytes into the circulation. In addition to the leakage of lymph due to increased pressure, lymphatic fistulae may form, allowing intestinal lymph containing serum proteins, Igs, chylomicrons and lymphocytes to drain directly into the intestinal lumen. The normal daily loss of serum protein into the gastrointestinal tract is <2%, but in the presence of intestinal lymphangiectasia may increase to 5–50%.⁹ Loss of serum proteins and lymphocytes leads to varying levels of hypogammaglobulinemia, lymphocytopenia and impaired cell-mediated immunity.

Clinical manifestations

Patients with primary IL usually present in the second or third decade of life with prominent edema due to lymphatic obstruction and/or protein-losing enteropathy-induced hypoalbuminemia and gastrointestinal complications. The edema is usually symmetric in the setting of major lymphatic obstruction, and asymmetric when peripheral lymphatic obstruction is present. The gastrointestinal manifestations include diarrhea, abdominal pain, distension, nausea, vomiting, malabsorption, and steatorrhea. Chylous ascites may be present as a result of blockage of serosal and mesenteric lymphatics; chylous pleural effusions may accompany blockage of the thoracic duct. The diagnosis is confirmed by the presence of hypoalbuminemia (<2.0–2.5 g/dL), lymphocytopenia (<1000–1500 cells/mm²) and a jejunal biopsy showing dilated lymphatics. Multiple biopsies may be necessary, because the changes may be patchy.

Clinical management

Treatment of primary IL focuses on therapy of the clinical manifestations, whereas treatment of secondary IL is directed to correcting the underlying cause. Peripheral edema is treated by postural drainage and

stockings. A low-fat diet reduces chylomicrons in obstructed lymphatics, thereby reducing intestinal lymphatic pressure, intestinal leakage of lymph, and the excretion of fat and protein. Replacing long-chain triglycerides with medium-chain triglycerides may reduce the steatorrhea and diarrhea, as medium-chain triglycerides are more water soluble and may be more readily absorbed into the portal venous system. Consistent with intact antigen-specific antibody responses,⁹ intestinal infections are not more common in IL.

WHIPPLE'S DISEASE

Diagnosis

Whipple's disease is a systemic infection caused by the Gram-negative actinomycete *Tropheryma whippelii*. Organisms may infect any region of the gastrointestinal tract mucosa, but most commonly the proximal small intestine. Bacilli are identified microscopically in the lamina propria as either free PAS-positive bacilli or as PAS-positive particles within macrophages. The particles represent intact or partially degraded bacilli, causing the macrophages to appear 'foamy.' *T. whippelii* have not so far been cultivated, therefore the diagnosis is based on the presence of clinical features of Whipple's disease and an intestinal biopsy containing PAS-positive, diastase-resistant, acid fast-negative macrophages. The biopsy also often shows dilated lacteals, probably due to compression of the lymphatics by the numerous large macrophages and neutral fat deposits and/or to compression of the mesenteric lymphatics by fibrosis. Other tissues also may contain PAS-positive macrophages, including lymph nodes, liver and spleen. When extra-intestinal PAS-positive macrophages are identified, histoplasmosis, nontuberculous mycobacterial infection and macroglobulinemia should be excluded, as PAS-positive macrophages may accompany these diseases as well.

Clinical manifestations

The classic presentation of Whipple's disease is that of a man (85% of cases) in his fourth or fifth decade with weight loss, diarrhea, abdominal pain and arthralgias. Complications of the gastrointestinal tract and the intestinal lymphatic system dominate the clinical presentation. Diarrhea with fat and carbohydrate malabsorption is present in the majority of patients, although the etiology of the diarrhea is unclear. Intestinal erosions and ulcerations, leading to significant bleeding, are also common. Extra-intestinal disease involves the central nervous system in approximately 10% of patients, most commonly manifesting as dementia, ophthalmoplegia and myoclonus. Migratory arthralgias usually predate the other symptoms, involve large joints, and do not demonstrate inflammation. Cardiac manifestations include pericarditis and endocarditis. Uveitis, retinitis, vitritis and optic neuritis are important ocular manifestations of Whipple's disease. Pleuritis, hyperpigmentation and lymphadenopathy also may be present in a substantial proportion of patients.

Treatment

Without antimicrobial therapy Whipple's disease is fatal. The recommended antibiotic regimen includes procaine penicillin G and streptomycin for 14 days, followed by trimethoprim-sulfamethoxazole for 1 year. Dietary folic acid should also be given.

HUMAN IMMUNODEFICIENCY VIRUS TYPE-1 INFECTION

The first cases of the acquired immunodeficiency syndrome (AIDS) were recognized in the USA in 1981, and human immunodeficiency virus type-1 (HIV-1) was identified as the causative agent in 1984. Since then, AIDS has emerged as the greatest pandemic in human history (Chapter 37). Although first recognized in the USA, the epicenter of the epidemic is sub-Saharan Africa, home to 10% of the world's population and by mid-2006 home to 64% of all persons with HIV-1 infection. All African countries (except Angola) have an estimated adult prevalence rate >10%, and in some countries (South Africa, Botswana, Lesotho, Swaziland and Zimbabwe) the rate approaches or exceeds 20%.¹⁰ Next to Africa, the Caribbean has the highest adult prevalence rate in the world. Countries with alarming and increasing rates of HIV-1 infection include India, Brazil and China.

Mucosal surfaces play a fundamental role in HIV-1 transmission, pathogenesis, natural history and vaccine strategy. Heterosexual transmission occurs through the genital mucosa, homosexual transmission through the lower and upper gastrointestinal tract mucosa, and vertical transmission via the upper gastrointestinal tract mucosa. Worldwide, approximately 85% of all HIV-1 infections are transmitted across the genital mucosa. Following inoculation onto a mucosal surface, translocation of virus from the apical surface into the lamina propria probably occurs through dendritic cell trapping, possibly via C-type lectins such as DC-SIGN, which bind HIV-1 gp120, and/or through epithelial cell transcytosis.¹¹ In the subepithelial lamina propria the virus encounters mononuclear target cells. However, in contrast to monocytes and macrophages in other tissues, resident intestinal macrophages lack the co-receptors necessary for HIV-1 infection.^{12, 13} Thus, lymphocytes are the initial mononuclear target cell in mucosal infection. The majority of these cells are activated memory T cells that express chemokine receptor 5 (CCR5), the co-receptor for the entry of CCR5-tropic HIV-1. Studies of simian immunodeficiency SIV (SIV) in macaques, a model for HIV-1 infection, as well as some studies of HIV-1 infection in humans, show rapid and massive depletion of intestinal CD4⁺ memory T cells within days to weeks of inoculation, regardless of the route of transmission. This depletion localizes to the effector region (lamina propria), persists in untreated subjects, is incompletely restored during antiretroviral therapy, and results in profound immunodeficiency. Viremia during early infection leads to rapid dissemination of virus to lymphoid organs, where persistent infection is established. T-cell activation via virus-induced cytokines and aberrant signaling predispose and enhance virus replication, which in the setting of rapid T-cell turnover promotes destruction of the immune system, perpetuating the immune deficiency and ineffective viral clearance. Rapid virus mutation and evolving glycosylation of the V1-V4 binding region of gp120 contribute to evasion of neutralizing antibodies and cytotoxic T cells. Blood monocytes express CD4, the primary receptor for HIV-1, and CXCR4, the co-receptor for CXCR4-tropic viruses, as well as CCR5, and probably participate in dissemination of the virus and serve as a reservoir in late-stage disease. These virus-induced cellular events predispose to the clinical manifestation of HIV-1 infection, particularly in the gastrointestinal tract.

KEY CONCEPTS

GASTROINTESTINAL MUCOSA IN HIV-1 DISEASE

- >> Route of HIV-1 entry in homosexual and vertical transmission
- >> Largest source of mononuclear target cells
- >> Site of earliest and most profound CD4 T-cell depletion
- >> Important site of HIV-1 replication and reservoir of HIV
- >> Location of opportunistic viral, bacterial, fungal and parasitic infections
- >> Critical target for HIV-1 vaccine strategies

Diagnosis

The diagnosis of HIV-1 infection is based on the detection of antibodies to viral antigens and/or the detection of viral components. Antibodies to HIV-1 are detected by enzyme immunoassay, which has a sensitivity of >99.5%. A positive or indeterminate test is confirmed by Western blotting. For an indeterminate Western blot, or to monitor the effect of therapy on viral load, a polymerase chain reaction (PCR)-based assay is used to detect viral RNA or proviral DNA. AIDS is diagnosed in a person with either HIV-1 infection plus a T-cell count <200 cells/ μ L, or HIV-1 infection plus an AIDS-defining opportunistic infection or a pathological process such as encephalopathy.

Clinical manifestations

The first clinical manifestation of HIV-1 infection is a mononucleosis-like syndrome that occurs 2–6 weeks after virus inoculation in 50–70% of acutely infected people. Infrequently, patients will progress rapidly (within months) to late-stage disease, with a prompt decline in CD4⁺ T cells and the appearance of opportunistic infections, particularly *Candida* infections of the oral cavity and esophagus.¹⁴ After seroconversion and the resultant decline in viremia in response to the anti-HIV-1 antibodies, symptoms of the acute syndrome subside and a prolonged period (median 10 years) of clinical latency follows,¹⁵ despite active virus replication and gradual destruction of the immune system. During this period, the number of CD4 T cells steadily declines and the patient becomes progressively more susceptible to an array of fungal, viral, parasitic and bacterial organisms. When CD4 T-cell numbers reach <200/ μ L, patients are particularly susceptible to *Pneumocystis jirovecii*, and when the number declines to <50 cells/ μ L they are at high risk for cytomegalovirus and *Mycobacterium avium* complex infections.¹⁶ The opportunistic organisms that cause gastrointestinal disease, particularly diarrheal illness, in immunosuppressed HIV-1-infected patients are listed in Table 74.1. In addition to infections, gastrointestinal lymphoma is more common in HIV-1-infected than uninfected persons. Kaposi's sarcoma was the most common neoplasm of the gastrointestinal tract at the outset of the epidemic, but is now rare in HIV-1-infected persons.

Treatment

Highly active antiretroviral therapy (HAART) combines reverse transcriptase inhibitor and protease inhibitor drugs into a powerful and highly effective antiviral therapy. HAART has revolutionized the

Table 74.1 Gastrointestinal pathogens associated with immunosuppression in HIV-1 infection

Organ process	Pathogens
Esophagitis, esophageal ulcer	<i>Candida albicans</i> ; herpes simplex virus; cytomegalovirus
Gastritis, gastric ulcer	Cytomegalovirus; <i>Mycobacterium avium</i> complex
Cholecystitis	<i>Cryptosporidium</i> ; cytomegalovirus; <i>Microsporidium</i> ; <i>Isospora belli</i>
Enteritis, intestinal inflammatory mass	<i>Cryptosporidium</i> ; <i>Microsporidium</i> ; <i>Isospora belli</i> ; <i>Mycobacterium avium</i> complex; <i>Salmonella</i> sp.; <i>Campylobacter jejuni</i>
Colitis, colonic inflammatory mass	Cytomegalovirus; <i>Cryptosporidium</i> ; <i>Mycobacterium avium</i> complex; <i>M. intracellulare</i> ; <i>Shigella flexneri</i> ; <i>Campylobacter jejuni</i> ; <i>Histoplasma capsulatum</i> ; adenovirus; herpes simplex virus (rectum)

treatment of HIV-1 disease, dramatically reducing the rate of death and the incidence of opportunistic infections as well as increasing the resolution of ongoing opportunistic infections. An additional benefit of HAART is a reduction in the use of antimicrobial agents, resulting in fewer *C. difficile* infections.

Standard antibiotic therapy remains an integral component of the management of HIV-1-associated opportunistic and nonopportunistic pathogens of the gastrointestinal tract. In this regard, the side effects, expense and availability of HAART, as well as HIV-1 resistance to HAART, require that many infections be treated with antibiotics. The management and antibiotic regimens for infectious diarrhea in HIV-1-infected persons have been described in detail elsewhere.^{14, 16}

GASTRITIS

Chronic gastritis is common in the general population, particularly in the aged. On clinical grounds chronic gastritis has been categorized as either type A, involving mainly the body of the stomach, or type B, mainly involving the antrum. In most individuals chronic gastritis is silent, although a variety of complaints, such as dyspepsia, fullness, nausea, vomiting, and abdominal pain, are sometimes attributed to it, and in some instances it may well be responsible for symptoms. Inflammation of these two areas of the stomach has different effects on normal physiology. Gastric acid is produced by parietal or oxyntic cells located in the body of the stomach. The antrum does not have parietal cells, but is enriched for endocrine cells that produce gastrin. Gastrin stimulates gastric acid secretion, and acid in turn inhibits gastrin.

Autoimmune gastritis falls into the type A category, and most instances of type B gastritis are due to *Helicobacter pylori* infection, but as noted below the two may be linked.

AUTOIMMUNE GASTRITIS/PERNICIOUS ANEMIA

Autoimmune gastritis occurs with increased frequency in individuals with other organ-specific autoimmune disorders, such as Hashimoto's thyroiditis, hypothyroidism, Graves' disease, insulin-dependent diabetes mellitus, Addison's disease, hyperparathyroidism, and vitiligo.¹⁷

A number of serologic tests are available if the diagnosis is suspected (Table 74.2), including serum anti-parietal cell antibodies, anti-intrinsic factor antibodies, serum gastrin, and serum pepsinogen I.¹⁸ Individuals with a positive anti-parietal cell antibody and a high gastrin have a high likelihood of having autoimmune gastritis.

The diagnosis is made by endoscopy and gastric biopsy. The histopathologic lesion consists of a mononuclear infiltrate in the gastric mucosa with variable atrophy of the gastric glands. Intestinal metaplasia is commonly associated and can be a precursor of gastric carcinoma. Gastric carcinoids can occur as well. Radiologic tests are not useful in either suspecting or making a diagnosis.

The major clinical manifestation of autoimmune gastritis is that of vitamin B₁₂ (cobalamin) deficiency, which results in a megaloblastic anemia (pernicious anemia) and a variety of neuropsychiatric manifestations. Dietary cobalamin is normally released by the acid proteolysis in the stomach. The released cobalamin then binds to a salivary B₁₂-binding protein called haptocorrin. Haptocorrin-cobalamin complexes are degraded by proteases in the intestine, and cobalamin then binds to gastric intrinsic factor; intrinsic factor-cobalamin complexes transit through the small intestine and bind to specific receptors on enterocytes in the distal ileum, triggering endocytosis and absorption. Autoimmune gastritis results in both achlorhydria and an absence of intrinsic factor, both of which contribute to the malabsorption of cobalamin. Cobalamin deficiency manifests as anemia, glossitis, neuropathy, depression, and memory impairment. Such individuals generally have a low vitamin B₁₂ level and an elevated serum gastrin. Diagnosis of vitamin B₁₂ malabsorption can be confirmed with a Schilling test with and without intrinsic factor. There are many other causes of cobalamin deficiency.

Pathophysiology

Autoimmune gastritis is one of the classic organ-specific autoimmune diseases. The major autoantigens recognized by T and B cells are the α and β subunits of H⁺-K⁺-ATPase, which is the acid pump that is localized on the canalicular or luminal surface of parietal cells.¹⁹ Parietal cells also produce intrinsic factor. Approximately 90% of patients with autoimmune gastritis have antibodies to parietal cells, and 50–60% have antibodies to intrinsic factor. Experimental models of autoimmune gastritis in the mouse seem to mimic the disorder closely, e.g., the same autoantibodies develop in mice with autoimmune gastritis as are seen in

Table 74.2 Biomarkers useful in the diagnosis of gastritis and gastric atrophy

	Autoimmune Gastritis	<i>H. pylori</i> Gastritis*	Comment
Serum gastrin	↑	↓	Increased in gastric atrophy
Serum pepsinogen I	↓	↓	Decreased in gastric atrophy
IgG antiparietal cell antibody	↑	-	Indicates autoimmune gastritis
IgG Anti- <i>H. pylori</i>	-	+	Indicates <i>H. pylori</i> infection

*When *H. pylori* affects the body of the stomach the pattern becomes more like that of autoimmune gastritis.

humans.²⁰ The autoantibodies are most likely not directly pathogenic but rather a reflection of T-cell autoreactivity, because in experimental models CD4 T cells are the effector cells that mediate tissue injury.²¹ The T-cell epitopes in the α and β chains of H⁺-K⁺-ATPase have been defined, and interestingly some murine T-cell epitopes overlap with those recognized by human T cells.²² These experimental models have also been crucial in the identification of the CD25⁺ (natural) T regulatory (Treg) cell. Autoimmune gastritis, as well as other organ-specific autoimmune diseases, arises in mice thymectomized at 3 days of life. In a series of classic studies this was found to be due to ablation of the development of CD25⁺ Treg cells.^{23,24}

A subset of patients with *H. pylori* gastritis can develop gastric atrophy.²⁵ CD4 T cells that respond to both H⁺-K⁺-ATPase and to *H. pylori* antigens have been identified in such patients,²⁶ suggesting that in some individuals autoreactive CD4 T cells can be activated by cross-reactive epitopes on *H. pylori* via molecular mimicry. In some environments, a high rate of *H. pylori* infection has been found in individuals with autoimmune gastritis, particularly in the younger age groups.²⁷ Because acid releases iron from food, individuals with gastric atrophy can present with iron deficiency anemia (as well as a megaloblastic anemia), and such iron-deficient individuals may be refractory to oral iron replacement.²⁸

Treatment

There is no treatment for autoimmune gastritis. The treatment of vitamin B₁₂ deficiency consists of injections of vitamin B₁₂ 100 µg IM monthly, or daily administration of cobalamin 1 mg orally.

HELICOBACTER PYLORI GASTRITIS

Type B chronic gastritis is mainly due to chronic *H. pylori* infection. *H. pylori* is a Gram-negative bacterium that persistently colonizes the mucous layer of the stomach, particularly in the antrum. The bacterium is usually acquired via oral ingestion in childhood and is transmitted within families, particularly in the setting of poor hygiene associated with lower socioeconomic conditions. Consequently, in most developing countries 60–80% of children less than 10 years of age are infected, whereas in industrialized countries less than 10% of similarly aged children are infected.²⁹ Although most *H. pylori* reside in the mucus, approximately 20% attach to the epithelium, probably facilitated by an adhesin, BabA, that binds to fucosylated Lewis B blood-group antigens

on gastric epithelial cells. Most *H. pylori* that cause disease contain a 29-gene 37 000-bp region called the *cag* pathogenicity island (*cagPAI*). The *cag* genes encode components of the type IV secretory system that is responsible for injecting the CagA protein into gastric epithelial cells, leading to the *cagPAI*-dependent induction of inflammatory responses through the activation of NF-κB.³⁰

Diagnosis

H. pylori is identified in the gastric mucosa using noninvasive and invasive tests. These include the urea breath test (sensitivity 90%; specificity 92%), serologic assay for IgG anti-*H. pylori* antibodies (sensitivity 91%; specificity 92%), Warthin–Starry staining (sensitivity 93%; specificity 99%), CLO test for bacterial urease (sensitivity 90%; specificity 100%), and histology for chronic inflammation (sensitivity 100%; specificity 66%).³¹ Overall, the serologic assay for *H. pylori* infection is the most convenient test for the detection of the bacterium and for monitoring therapeutic effectiveness, as the antibody titer will decline approximately 50% by 6 months after successful eradication.³²

Clinical manifestations

Colonization of the stomach by *H. pylori* is the major risk factor for gastritis, peptic ulceration, gastric adenocarcinoma, and gastric lymphoma. Virtually all infected persons develop gastritis, but the course of infection is influenced by *H. pylori*- and host-specific factors. Patients with antral-dominant gastritis have higher gastric acid output and are predisposed to duodenal ulcers but not gastric cancer. In contrast, those with gastritis involving the body of the stomach are predisposed to gastric ulceration and the loss of parietal cells, achlorhydria, gastric atrophy, intestinal metaplasia, dysplasia and gastric cancer.³³ Carcinogenesis is influenced by host genetic diversity, including polymorphisms in the *IL-1β* and *TNF-α* cytokine genes, which are associated with increased corpus cancer, possibly through the acid inhibitory activity of IL-1β and TNF-α.³⁴ Among *H. pylori*-infected persons the cumulative long-term risk for ulcer disease varies between 2% and 10%, depending on the study population. In developed countries, the overall risk for developing gastric cancer is estimated to be increased sixfold among *H. pylori*-infected persons. Importantly, *H. pylori* loses its ecological niche in the setting of achlorhydria and gastric atrophy; consequently, it is difficult to detect in persons with gastric cancer.

KEY CONCEPTS

CLINICAL MANIFESTATIONS OF *H. PYLORI* INFECTION (INCIDENCE)

- >> Chronic gastritis (100%)
- >> Gastric and duodenal ulcer (2–10%)
- >> Gastric adenocarcinoma (23%)
- >> Gastric mucosa-associated lymphoid tissue (MALT) lymphoma (<3%)
- >> Iron-deficiency anemia (not known)

The incidence of *H. pylori*-associated gastric lymphoma is probably less than that of gastric adenocarcinoma, but unlike gastric adenocarcinoma, in many *H. pylori*-infected patients gastric lymphoma can be eradicated with antibiotic therapy.

Treatment

In countries with a high prevalence of *H. pylori* infection, the cost and risks associated with antimicrobial treatment do not justify mass eradication programs. However, therapy is indicated in patients with *H. pylori*-related symptoms, or complications such as peptic ulcer, mucosa-associated lymphoid tissue (MALT) lymphoma, or a first-degree relative with *H. pylori* infection. A triple-drug regimen for 2 weeks is usually necessary for successful eradication. The combination of bismuth, tetracycline and metronidazole is highly effective. However, the widespread use of antibiotics has resulted in the development of resistant strains, which may require follow-up evaluation for the persistence or recurrence of symptoms.

CELIAC DISEASE

Celiac disease is a chronic inflammatory disease of the small intestine induced in genetically susceptible individuals by ingestion of the cereal grains of wheat, barley, and rye that collectively are known as 'glutens.' The inflammation is accompanied by a variable degree of villous atrophy and malabsorption of nutrients, but has many manifestations in other organ systems. It has been called a variety of names, including celiac sprue, gluten-sensitive enteropathy, and nontropical sprue. Celiac disease occurs worldwide and the prevalence seems to range between 1 in 100 and 1 in 300 individuals in various parts of the world.³⁵ In the USA the prevalence is estimated to be 0.5–1% of the population (http://consensus.nih.gov/cons/118/118cdc_intro.htm). As in many other immune-mediated inflammatory diseases, there are environmental, genetic, and immune components in its pathogenesis. Celiac disease is widely considered an autoimmune disease due to serologic reactivity to tissue matrix autoantigens.

Clinical presentations

The classic gastrointestinal presentation of celiac disease is chronic diarrhea, weight loss or failure to grow, malabsorption, and abdominal distension, particularly in children. This presentation is now recognized

to be uncommon.^{35, 37} Celiac disease manifestations are quite variable, can start at any age, and can affect organ systems other than the gastrointestinal tract. Other gastrointestinal presentations that can occur include chronic constipation, abdominal pain, bloating, and anorexia. Nongastrointestinal manifestations are shown in Table 74.3 and clearly can affect multiple organ systems. Patients with these manifestations have few or no GI symptoms, and so considering the diagnosis can be quite challenging. In addition to the entities shown in Table 74.3, a number of neuropsychiatric conditions have been associated with celiac disease, including fatigue, depression, anxiety, peripheral neuropathy, cerebellar ataxia, other neurologic syndromes, and migraine headaches.

Dermatitis herpetiformis is now considered a dermatologic manifestation of celiac disease.³⁸ This condition consists of a pruritic, vesicular, symmetrical rash, particularly on extensor surfaces of the limbs. The diagnosis is made by biopsy, which demonstrates acute inflammatory infiltrates below the dermis and granulated deposits of IgA and complement at the basement membrane by immunohistochemistry. Gliadin peptides have not been formally proven in these immune complexes, but are inferred by the loss of IgA deposits with a gluten-free diet. Most patients with dermatitis herpetiformis have no GI symptoms. The response to a gluten-free diet is slow and takes many months. Anti-inflammatory agents such as dapsone are frequently used for rapid symptom relief. If a biopsy diagnosis of dermatitis herpetiformis is made, there is no need for small bowel biopsy to confirm celiac disease because the two diagnoses are considered equivalent.

Serologic tests

Serologic tests are available to help in the diagnosis of celiac disease. These tests can be used to identify symptomatic individuals who should have a small-intestinal biopsy. Although anti-gliadin antibodies have for many years been measured for this purpose, these antibodies are not sufficiently sensitive or specific and have been largely replaced by the newer tests discussed below.

Endomysial antibodies (EMA) are detected by immunohistochemical tests that detect IgA binding to a connective tissue component surrounding smooth muscle fibers. This test is a more refined version of the older reticulin antibody test. It is operator dependent and thus somewhat subjective, but has high sensitivity and specificity (Table 74.4). The specific antigen detected by these IgA antibodies has been identified as tissue transglutaminase, which has allowed an ELISA to be developed

Table 74.3 Multisystemic presentations of celiac disease

Dermatitis herpetiformis	Elevated transaminase test
Dental enamel hypoplasia of permanent teeth	Infertility
Osteopenia/osteoporosis	Autoimmune endocrine disorders
Delayed puberty	Epilepsy with occipital calcifications
Short stature	Neuropsychiatric symptoms
Iron deficiency anemia	Aphthous stomatitis
	Depression

Table 74.4 Serologic tests for celiac disease (From Farrell RJ, Kelly CP. Celiac sprue. *N Engl J Med* 2002;346:180–188)

	Sensitivity (%)	Specificity (%)
IgA anti-gliadin antibody	75–90	82–95
IgG anti-gliadin antibody	69–85	73–90
IgA anti-endomesium (EMA)	85–98	97–100
IgA anti-tissue transglutaminase (TTG)	90–98	94–97

for its measurement. The initial versions of this ELISA used a guinea pig protein, but the second generation of the test now utilizes human recombinant tissue transglutaminase, which is preferred. IgA anti-tissue transglutaminase (TTG) has as high a sensitivity and specificity as the EMA. Either is suitable as a screening assay. Because both of these assays detect IgA antibodies, IgA deficiency is a possible confounder. In symptomatic individuals concomitant measurement of serum IgA can be helpful to interpret a negative result. Both assays can be falsely negative in young children. These serologic tests become negative when celiac patients follow a gluten-free diet. Thus, some clinicians monitor compliance with the diet by periodically re-testing the IgA EMA or IgA TTG.

The application of these newer serologic tests to blood donor populations has identified many positives,³⁵ and this is the basis of the estimates that 0.5–1% of the population in the USA might have celiac disease. Only a small percentage of the total estimated cases are diagnosed, which has led to the analogy of celiac disease as an iceberg, with diagnosed cases representing only the tip. Such screening of healthy populations and of those at risk has detected individuals with positive serologic tests but no symptoms. Some of these individuals have an abnormal small bowel biopsy compatible with celiac disease, and this group has been termed ‘silent’ celiac disease. Other individuals have a normal small bowel biopsy despite positive serologies and are thought to have latent celiac disease. Some of the latter individuals will develop typical small intestinal lesions over time, but others do not (Fig. 74.1). The natural history of these two groups is unclear, and whether the ‘silent’ group should follow a gluten-free diet is at present unknown (http://www.worldgastroenterology.org/globalguidelines/guide13/g_data13_en.htm#sec08).

Because this is the age of the Internet, it is not uncommon that individuals with various symptoms diagnose themselves as having celiac disease. They often then put themselves on a gluten-free diet and later appear in the physician's office wanting to know whether they do indeed have celiac disease. This represents a clinical conundrum, in that both the serologic tests and the biopsy return to negative or normal on a gluten-free diet. One approach is to test such individuals for HLA DQ2 and DQ8, which if negative virtually excludes the diagnosis of celiac disease. Another approach is to put them back on a gluten-containing diet and follow their serologic reactivity. Individuals with positive serology could undergo a small bowel biopsy to establish the diagnosis. There are individuals who do not have celiac disease but have gluten intolerance, i.e., are symptomatic when eating gluten-containing foods. Such individuals can safely remain on a gluten-free diet for life and may be able to tolerate small amounts of gluten without symptoms.

Diagnosis/histology

A small bowel biopsy is obligatory to confirm a diagnosis of celiac disease. The histologic features include increased numbers of intraepithelial lymphocytes, villous shortening or flattening, crypt hyperplasia, and infiltration of the lamina propria with lymphoid cells. These changes form a spectrum from mild to severe, and this spectrum can be quantified using a numerical grading scale called the Marsh criteria. These histopathologic changes are maximal in the proximal small intestine and in severe cases may extend down into the ileum. However, the lesions can transition back to normal, even in the upper jejunum. This variation in the extent of small bowel affected probably accounts for the variability in symptoms seen in patients. Endoscopic biopsies sample only the second and third portions of the duodenum, and thus at present there is no way to measure the length of small bowel affected.

Biopsy is part of the gold standard for diagnosing celiac disease, but other diseases can share similar histopathologic features, including tropical sprue, HIV enteropathy, immunodeficiency states, radiation damage, graft-versus-host disease, chronic ischemia, Crohn's disease, Zollinger–Ellison syndrome, and eosinophilic gastroenteritis, to name but a few. Many of these alternative diagnoses can be eliminated by the clinical situation. Thus, in addition to a compatible small intestinal biopsy, a clinical response to a gluten-free diet is required for a definitive diagnosis to be made. This response should include both symptomatic improvement and conversion of the serologic tests to negative.

Genetics

It has long been recognized that there is a strong genetic component in celiac disease. For example, the prevalence among first-degree relatives is 10%, and the disease concordance in identical twins is up to 70%. There is a strong link to the HLA locus, and within that locus the disease is linked specifically to the DQ2 and DQ8 class 2 alleles (Chapter 5).^{39, 40} DQ2 is formed by an α chain encoded by DQA1*05 and a β chain encoded by DQB1*02 and is present in 90–95% of patients with celiac disease. The DQ8 α chain is encoded by DQA1*03 and the β by DQB1*0302 and is present in the 5–10% of celiac patients not bearing DQ2. These alleles form an antigen-binding MHC class II molecule on the surface of antigen-presenting cells that has high affinity for the gluten peptides that trigger disease. Based on the crystal structure of a DQ2–gluten peptide complex, this binding is enhanced by deamidation of selected glutamines to negatively charged glutamic acid residues, which in turn is accomplished by tissue transglutaminase.⁴¹ Populations with a low frequency of DQ2 and DQ8, for example in Japan and China, have low

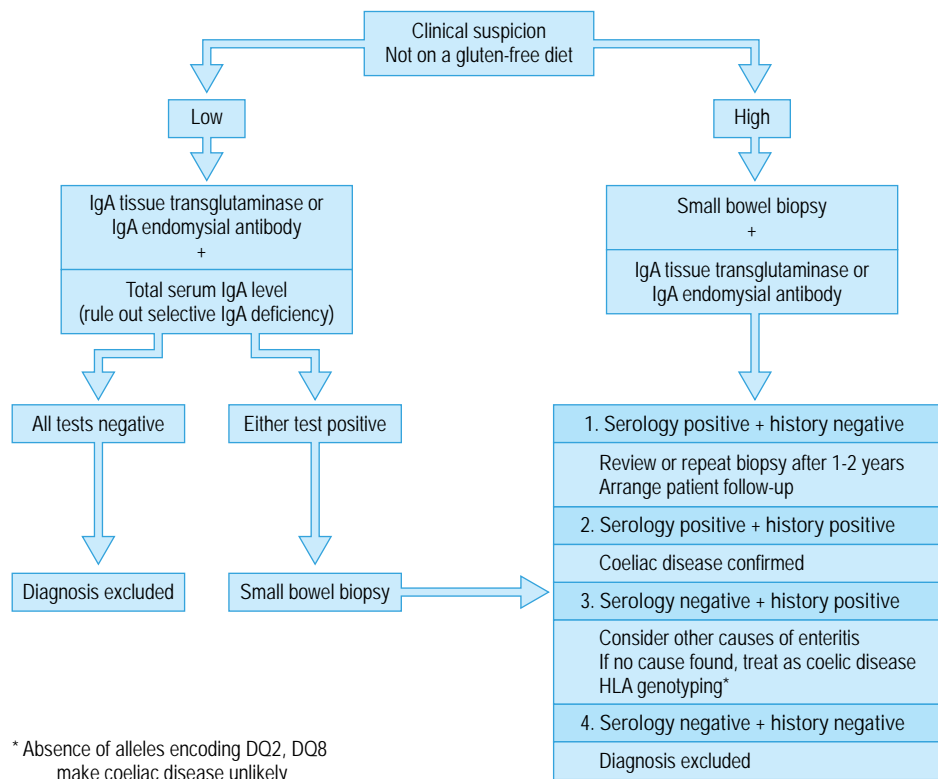

Fig. 74.1 Diagnostic algorithm for celiac disease.

frequency of celiac disease. However, these HLA genes are necessary albeit not sufficient for celiac disease to occur, because in North America and Europe some 30–40% of the population is DQ2 positive. These two alleles account for an estimated 30% of the risk for celiac disease, and thus other genetic loci are probably involved. There are limited data on what these other genes are, but quantitative gene locus mapping has identified at least one locus on chromosome 5q31–33.⁴² Interestingly, this same locus is implicated in other chronic inflammatory diseases.

Environmental/dietary factors

Exposure to cereal grains from wheat, barley, and rye is obligatory for celiac disease to manifest, even in genetically susceptible individuals. This is proven by the absence of lesions and symptoms in individuals with celiac disease on a gluten-free diet. Wheat, barley, and rye share a common ancestry in the grass family. Oats are more distantly related and are tolerated in the diet of most celiac disease patients. By definition, gluten refers only to the cereal grain proteins of wheat; the analogous proteins in rye are the hordeins, and in barley are the secalins. However, all three have been collectively and loosely referred to as gluteins or gluten peptides. These proteins are responsible for the elasticity and other favorable cooking properties of these grains.

Gluten proteins from all three sources share a high proline and glutamine content, which renders them relatively resistant to degradation by mammalian digestive enzymes. This resistance allows gluten peptides

to remain of a size able to bind to DQ2 or DQ8 and stimulate CD4 T cells. Indeed, T cells have been isolated from the mucosa of patients with celiac disease that react to gluten peptides in the context of HLA-DQ2 or DQ8.⁴³ T cells isolated from nonceliac mucosa, even of individuals that are DQ2 positive, do not contain gluten reactive T cells.

Pathogenesis

There is strong evidence that lamina propria CD4 T cells play an important role in the pathogenesis of the celiac lesion.⁴⁴ Because these T cells are separated from the gluten peptides by the epithelial layer, such peptides must cross the mucosa in some fashion, but the mechanism of such translocation is unclear. In the lamina propria tissue transglutaminases act on the gluten peptides to deamidate them, converting selected glutamines to negatively charged glutamic acids.⁴⁵ The deamidated gliadin peptides have been shown to have a much greater ability to bind to DQ2 and DQ8 antigen-binding grooves that have positively charged binding pockets. In fact, CD4 T cells in the lamina propria of celiac disease patients recognize mainly deamidated gliadin peptides. Although there is great variation in the specific peptide sequences activating T cells obtained from different individuals, a 33-mer peptide has been identified that can activate a large proportion of T-cell clones isolated from celiac mucosa.⁴⁷ This motif can be related back to the DQ2 binding groove, whose crystal structure is known.⁴⁶ The number of wheat, barley, and rye proteins with the correct binding motifs for DQ2 or

DQ8 have been estimated to be a small fraction of the total sequences potentially present in these grains.⁴⁸ The gliadin-reactive CD4 T cells in the lamina propria of celiac disease patients produce interferon (IFN)- γ , suggesting that they are polarized to a Th1 effector phenotype.⁴³ Such cells are known to activate a variety of downstream inflammatory cytokines and upregulate tissue metalloproteinases, which presumably results in the actual lesion. However, very little information is available about these downstream effects. IFN- γ is also known to increase gut permeability and hence might increase the translocation of more peptides, resulting in a vicious circle. The event that triggers this whole cascade is as yet unclear, but gastrointestinal infections with enteric viruses, for example, have long been suspected as a crucial trigger. The lamina propria is known to contain CD4 Treg cells, but little is known about the role they play in celiac disease.

Less is known about what role the intraepithelial lymphocyte (IEL) plays in disease pathogenesis. Increased numbers of IEL are a consistent feature of the histopathology of celiac disease. Intraepithelial lymphocytes are mainly CD8 T cells that bear either a $\gamma\delta$ or an $\alpha\beta$ TCR. The numbers of IEL return to normal on a gluten-free diet, and increases in IEL can occur within hours of a gluten challenge. However, there is no evidence that the T-cell receptors on these CD8 T cells are responding directly to gliadin peptides. Rather, this response may be secondary to the lamina propria CD4 T-cell response. IL-15 has been shown to expand certain IEL subsets, including those that bear natural killer (NK) receptors such as NKG2d and CD94.⁴⁹ These NK receptors are known to interact with nonclassic MHC class I molecules whose expression is induced by cellular stress or by IFN- γ . The epithelial cells of patients with celiac disease produce high amounts of IL-15; this has been postulated to result in the expansion of IEL expressing these NK cell receptors, which then are cytotoxic for epithelial cells expressing the relevant ligands.⁵⁰ Expansion of such NK-like IEL has been identified in individuals with celiac disease that is refractory to a gluten-free diet.⁵¹

Treatment

The treatment of celiac disease is a gluten-free diet for life, i.e., total avoidance of wheat, barley, and rye in the diet. Oats are allowed, at least in moderate amounts, although there are concerns that oats may be contaminated with these other grains, making them deleterious to some patients. Because gluten is present in a wide variety of foods, education of the patient is required. The ideal way to accomplish this is a consultation with a dietitian who is extremely knowledgeable about gluten-free diets. Not all dietitians have such expertise, and thus a patient can be referred to a variety of local and national support groups who can provide the required information. Patients starting such a diet should be followed with repeated visits to the physician for guidance, encouragement, and to enhance compliance. Many clinicians follow the IgA anti-tissue transglutaminase as a measure of the adequacy of a gluten-free diet: this test should return to normal if the diet is strict. Alternate forms of therapy that might allow continued ingestion of gluten are under study. These include the production of genetically modified wheat that lacks the relevant peptides, bacterial endopeptidases that degrade the gliadin peptides, drugs that might block intestinal tissue transglutaminase, competitive peptides that might block HLA-DQ2 or -DQ8, and anti-IL-15.

REFRACTORY CELIAC DISEASE

A small subset of patients with confirmed celiac disease fail to respond to a gluten-free diet. The most common cause is continued ingestion of gluten, either deliberately or inadvertently. However, some other conditions that need to be considered include autoimmune enteropathy,⁵² lymphoma, ulcerative jejunoileitis, collagenous sprue, or refractory sprue. Patients with refractory sprue can demonstrate abnormal oligoclonal expansions of intraepithelial T cells, a condition that has been called 'cryptic intestinal T-cell lymphoma' and which has a poor prognosis. These oligoclonal expansions can progress into enteropathy-associated T-cell lymphoma (EATL), in which there are monoclonal expansions of these IEL.⁵³ Patients with refractory sprue may benefit from treatment with corticosteroids, an immune modulator such as azathioprine, cyclosporine, or infliximab.⁵⁴ Fortunately, this entity is uncommon.

INFLAMMATORY BOWEL DISEASE

Crohn's disease and ulcerative colitis are two related but distinct chronic inflammatory diseases of the intestine. Because they have overlapping features, the two are grouped together under the term 'inflammatory bowel disease' (IBD). Crohn's disease is a transmural inflammation that can affect any part of the intestine from the mouth to the anus, but most commonly the distal ileum and colon. The inflammation tends to be focal and discontinuous, with areas of involvement alternating with normal intestine ('skip lesions'). Granulomas in the lesions are a hallmark, but are not needed for diagnosis because they occur in less than half of patients. Mucosal ulcerations are fissuring, i.e., penetrate deep into the intestinal tissue, and can erode through the gut wall to form fistulas or abscesses. Ulcerative colitis is restricted to the rectum and colon and the inflammation and ulceration affect only the surface mucosa. Ulcerative colitis starts in the rectum and extends proximally and contiguously into the colon to a variable extent. The inflammation typically does not affect the deeper layers of the colon, except when the disease becomes very severe.

Clinical presentations

Both diseases affect children and adults, with a peak incidence in the second to third decades, but both can occur at any age. Crohn's disease presents with abdominal pain, watery diarrhea, weight loss, and fever. Ulcerative colitis usually presents as rectal bleeding and diarrhea, but can present with either of these alone. A subset of patients develop extra-intestinal manifestations such as arthralgias, arthritis, uveitis, or skin lesions, and sometimes these are the dominant presenting feature. The prevalence of each disease is approximately 150 per 100 000 population in the USA. It is likely that several subtypes of each disease exist that are currently placed together under these two diagnoses, in that data from experimental models of IBD indicate that multiple genetic deficiencies and different immunologic mechanisms can result in IBD.⁵⁵ Research is ongoing to define such disease subgroups using genotype and immunophenotype stratifications.⁵⁶

Diagnosis

The diagnosis of these disorders is based on the clinical symptoms, radiologic imaging, endoscopy, and biopsies. The radiologic tests include barium contrast studies of the colon, stomach, and small intestine, as well as various CT scans of the abdomen and pelvis. A recent addition for the diagnosis of Crohn's disease has been wireless capsule endoscopy, which can image the mucosa of the entire small intestine. Endoscopy is a mainstay of diagnosis and management. However, tissue biopsies or histopathology of intestinal resections are optimal for diagnosis. Serologic tests are available, but their utility for diagnosis has not been established.

Serology

A number of autoantibodies have been found in patients with ulcerative colitis, e.g., multiple autoantibodies to colon epithelial cells have been identified, the best-characterized of these being an antibody to tropomyosin.⁵⁷ However, the only antibody in clinical use is serum IgG pANCA (perinuclear anti-nuclear cytoplasmic antibody). This antibody is detected by reactivity to methanol-fixed neutrophils and has a characteristic staining of the perinuclear membrane rather than the cytoplasm, as seen with other ANCAs. pANCA is produced by lamina propria B cells from the lesions of ulcerative colitis, and probably represents cross-reactivity to an antigen of the microbiota.⁵⁸ pANCA has no known role in disease pathogenesis. pANCA sensitivity and specificity are not high enough to use alone as a diagnostic test. Serum pANCA may have some prognostic value, in that patients with high-titer pANCA tend to have more severe ulcerative colitis, and a higher proportion of pANCA-positive patients develop chronic pouchitis after colectomy.

Autoantigens have also been found in subsets of patients with Crohn's disease, but again there is no convincing evidence that these play a role in the pathogenesis. Antibodies to multiple microbial antigens have been detected in the serum of patients, and these may have some clinical utility.⁵⁹ The best-defined of these is IgG and IgA anti-*Saccharomyces cerevisiae* (ASCA). In addition, patients with Crohn's disease have also been found to selectively express IgA anti-*E. coli* outer membrane protein C, IgA anti-*Pseudomonas fluorescens* I2, and IgG anti-CBir1 flagellin to a greater extent than do patients with ulcerative colitis or disease controls (Table 74.5). It remains to be proved that these tests can be used for diagnosis, for example to distinguish IBD as Crohn's disease. However, these antimicrobial antibodies appear to have some prognostic value, in that patients with high titers have a higher rate of complications as well as a higher frequency of surgery than do patients without these antibody

reactivities.⁶⁰ Serum IgG anti-flagellin reactivity, which has only been recently discovered,⁶¹ is independently associated with a poor prognosis.⁶² Combining these antibody reactivities considerably improves their sensitivity and specificity for diagnosing Crohn's disease and ulcerative colitis, and such a panel is commercially available.

Histopathology

Because both diseases are within reach of the endoscope, endoscopy with biopsy of affected tissue is the mainstay of histopathologic analysis. Endoscopic biopsies are small and sample only the superficial mucosa, hence it can be difficult to distinguish ulcerative colitis from Crohn's disease by biopsy alone. However, some histopathologic features can be identified in such small biopsies that are characteristic of IBD, including distortion of the crypts, infiltration of lamina propria by mononuclear cells and neutrophils, increased numbers of plasma cells, the location of plasma cells below the base of the crypts, and Paneth cell metaplasia. The hallmark of the lesions of ulcerative colitis is that the inflammation remains confined to the mucosa and immediate adjacent submucosal area, whereas in Crohn's disease the inflammatory infiltrates penetrate through the entire wall. However, these features are only evident in surgical resections. Analysis of such resections has revealed that the lymphoid infiltrates involves all the major leukocyte cell types including B cells, T cells, plasma cells, macrophages, neutrophils, and eosinophils. Among the plasma cells, those producing IgG and IgM are increased more than those producing IgA. Analysis of the TCR repertoire of such resections shows that it is a diverse polyclonal repertoire and is not significantly different in diseased as opposed to unaffected mucosa.

Genetics

It has long been recognized that these diseases have a genetic component. For example, Crohn's disease has a high concordance between monozygotic twins, and both Crohn's disease and ulcerative colitis occur with a higher frequency in family members of patients and in certain ethnic groups, such as Jews.⁶³ Interestingly, certain of the serologic markers of IBD discussed above appear with a higher frequency in unaffected family members of seropositive patients.⁶⁴ A variety of candidate genes have been linked to IBD, including some MHC genes, but the associations have generally been weak and inconsistent among different populations.

A major breakthrough in the genetic basis of IBD came with the advent of genome scanning using microsatellite markers (Chapter 101). In this technique a trait such as the presence of a disease can be linked to

Table 74.5 Serologic tests in inflammatory bowel disease

Antibody to	Isotype	UC	% positive	
			Crohn's	Control
pANCA	IgG	30–70	25	<5
ASCA	IgG, IgA	6–14	40–70	–
I2	IgA	–	50	–
OmpC	IgA	–	55	–
CBir1 flagellin	IgG	6	50	8

a specific location along the chromosomes where one or more genes reside that affect the expression of that trait. An advantage of this approach is that one does not need to know the identity of the gene to find an association; a disadvantage is that the approach does not identify the specific gene involved, but only a chromosomal region, which usually encompasses many genes. Despite these difficulties, a major triumph of this approach has been the identification of NOD2/CARD15 as a major susceptibility gene for Crohn's disease but not ulcerative colitis.^{65,66} The gene encodes an intracellular pattern recognition receptor for the muramyl dipeptide component of bacterial peptidoglycan. There are three dominant mutations in the carboxy end of the molecule that are associated with the development of Crohn's disease, one of which is a truncation mutation. The exact mechanism of disease susceptibility caused by the CARD15 gene is as yet unknown but under intense study. However, the identification of a pattern recognition receptor as a susceptibility gene for Crohn's disease is coherent with the abundant data from preclinical experimental models, which is discussed in the next section. Genome scanning has identified many other loci linked to either Crohn's disease, ulcerative colitis, or both, and other candidate genes are being identified.⁶⁷

Environmental factors

In addition to genetic susceptibility, it has long been recognized that there is a major environmental influence on the expression of these diseases. One of the major environmental influences is geographic location. IBD is a disease of westernized, urbanized populations and is rare in the Third World. For example, until recently these diseases had been rare in India and China, but as these countries industrialize IBD is now emerging in both. Interestingly, immigrants into the industrialized countries from less developed areas do not develop IBD; rather, it is their children who are born and raised in the western environment who develop these disorders. The environmental factors that lead to increased susceptibility to these diseases in western countries is unknown, but one interesting hypothesis is that there is a relative lack of appropriate stimulation of the immune system by the flora or by enteric pathogens – the hygiene hypothesis. Only two factors have been identified that can strongly influence the development of either Crohn's disease or ulcerative colitis. Smoking increases susceptibility to Crohn's disease and, conversely, nonsmoking has been associated with a higher frequency of ulcerative colitis. Smoking also affects disease course, in that individuals with Crohn's disease who continue to smoke require immune suppression more frequently.⁶⁸ The second factor is appendectomy performed for appendicitis, which reduces the frequency of ulcerative colitis development but has no effect on Crohn's disease incidence.

Pathophysiology

An infectious etiology for both Crohn's disease and ulcerative colitis has long been postulated, but no agent has been consistently identified. One cannot exclude infection with an unknown organism, and certainly the experience with *Helicobacter pylori*-induced gastritis shows that such an organism can elude detection for decades. However, the bulk of the data favors that the inflammatory bowel diseases are disorders of host-microbe interactions in the intestine.⁶⁹ This concept is still evolving and has been strongly influenced by results from many experimental models

of IBD. These models have provided important hypotheses that need to be confirmed in human studies. The microbiota itself is poorly understood and largely undefined. Current estimates are of 500–1000 species and ~8000 strains.⁷⁰ With regard to host immune interactions with the microbiota, innate, adaptive, and regulatory cells all are involved in the response.

Experimental models demonstrate that gene defects in each of the innate, adaptive, and regulatory compartments can result in IBD.⁷¹ In many models there are abnormalities of more than one component, e.g., IL-10-deficient mice have abnormalities in both innate and regulatory components. Multiple genes are known to be involved in susceptibility to IBD in humans as well. Because humans are unlikely to have the absolute genetic defects that have been induced in experimental models, human disease is more likely to represent partial (10–20%) defects in multiple genes, rather than a major defect in one or a few genes. In combination, such partial defects can result in the phenotype of Crohn's disease or ulcerative colitis, but the individual contribution of each gene will be difficult to detect because each is a small contributor.

With regard to the adaptive immune system, a consistent observation in experimental models has been that the CD4 T cell is the major effector cell leading to chronic intestinal inflammation. Crohn's disease is considered an example of a CD4 Th1-mediated disease. Supporting this idea are increased levels of IL-12 p40, IFN- γ , and STAT4 in active lesions. The recently described IL-23-dependent, CD4 Th17 effector cell lineage may also play a role, in that both IL-23 and IL-17 are increased in the lesions of Crohn's disease, and the CD4 Th17 subset has been shown to play an important role in disease progression in experimental models of colitis. In experimental models the immune reaction is directed at antigens of the microbiota, and the same appears to be the case in patients with Crohn's disease, as demonstrated by the multiple antimicrobial antibodies mentioned above.

Ulcerative colitis does not fit well into the Th1/Th2 paradigm but some have suggested it to be a Th2-like disease. Although IL-4, the hallmark Th2 cytokine, is not increased in the lesions of ulcerative colitis, IL-5 and possibly IL-13 are increased. In one experimental model, an ulcerative colitis-like disease was determined to be due to an IL-13-dependent, CD1d-restricted NK T-cell effector mechanism. A similar mechanism has been postulated for human ulcerative colitis.⁷²

Inflammatory cytokines are increased in the active lesions of both UC and CD, including IL-1, IL-6, TNF- α , and many others. These are produced by macrophages and other innate cells. This assortment is no different from those produced in any inflamed tissue. Macrophages present in the normal intestine do not produce cytokines and have down-regulated many surface molecules, such as CD14, a state that has been called 'inflammatory anergy.'⁷³ In contrast, the macrophages producing inflammatory cytokines in the lesions of IBD are CD14⁺ and appear to be recent immigrants into the gut from the monocyte pool in the blood. Thus, inhibition of leukocyte trafficking into the intestine is an attractive target for therapy. The inflammatory cytokines have many detrimental effects on tissues, such as recruitment of granulocytes, induction of metalloproteinases that can destroy tissue stroma, etc. TNF seems to play an important central role in this inflammatory cytokine cascade, in that monoclonal neutralization of TNF in patients with both CD and UC can result in rapid inhibition of the inflammatory response. Although these cellular contributors to tissue injury are known, the exact molecular mechanisms underlying tissue injury in these two diseases are yet to be defined.

Medical treatment

The mainstays of medical therapy are nonspecific anti-inflammatory drugs (NSAIDs) to inhibit the inflammatory cascade. These include 5-aminosalicylic acid agents and topical steroids such as budesonide. Patients not responding to this first line of therapy are usually placed on oral or parenteral steroids. Because a significant fraction of patients do not respond to steroids or cannot be weaned off of them, immune modulators are often used, including 6-mercaptopurine or its imidazole derivative azathioprine. These agents act slowly but can allow patients to come off steroids, or at least minimize the dose required in 50–70% of steroid-refractory or steroid-dependent cases. Methotrexate has shown some efficacy as a maintenance agent in Crohn's disease, but does not appear effective in ulcerative colitis. Cyclosporine has shown some efficacy in fulminant ulcerative colitis but is too toxic for prolonged use, and is used as a bridge to one of the traditional immune modulators. Cyclosporine has shown no efficacy in Crohn's disease. Monoclonal antibodies to TNF have shown efficacy in both Crohn's disease and more recently in ulcerative colitis, and are used for patients who are not responding to the standard therapies listed above. The indications for anti-TNF and other biologics are continuing to evolve, and their use earlier in the disease course is being explored. Many other strategies are being developed for the medical management of inflammatory bowel disease, as well as for other immune-mediated diseases, such as inhibitors of leukocyte migration by blockade of adhesion molecules.

Surgical treatment

Surgery is generally reserved for the complications of inflammatory bowel disease rather than as a primary therapeutic modality. A common indication for surgery is disease that does not respond to any of the medical therapies or, in the case of ulcerative colitis, becomes fulminant. For ulcerative colitis, a complete colectomy is required. The operation of choice is a complete proctocolectomy with construction of a neorectum or 'pouch' from the distal ileum, which is attached to the anal canal. Unfortunately, inflammation of this ileal pouch can occur in up to 50% of patients receiving this operation for ulcerative colitis, although pouchitis does not occur in patients having a colectomy for hereditary polyposis. Most patients with pouchitis respond to a short course of antibiotics, but others require many of the same medications used for treatment of the primary disease.

In individuals with Crohn's disease, surgery is reserved for complications of the disease, such as stricture with obstruction, hemorrhage, fistula, abscess, or lack of response to medical therapy. The affected segments are resected and the unaffected bowel reconnected. There is a high rate of recurrence after surgery, which is dependent on the presence of the fecal stream. Such disease often recurs at the anastomosis, e.g., in the neoterminal ileum after an ileocecal resection. At present there is no medication that will prevent the recurrence of Crohn's disease.

CONCLUSION

The broad spectrum of immune disorders affecting the gastrointestinal tract reflects its unique role as the major interface between the host immune system and the microbial world. The mucosal immune system also has to deal with the large quantities of foreign antigens present in

food. Progress has been made in understanding how the mucosal immune system is able to deal with this complex environment while maintaining intestinal homeostasis. These various disorders represent instances in which the normal mucosal immune mechanisms have failed in one way or another. The study of these disorders is important because they are human diseases, but they also provide a window into how the gut immune system accomplishes its amazing ability to balance nonresponsiveness to the microbiota and to food while retaining the ability to actively respond to intestinal pathogens.

Inflammatory hepatobiliary cirrhosis

75

Carlo Selmi, Michael P. Manns, M. Eric Gershwin

Inflammatory hepatobiliary disease is a generic term that comprises conditions presenting a complex noninfectious etiopathogenesis characterized by chronic inflammatory infiltrate and autoimmune features.¹ Among these, the main distinction is based on the target tissue, whether this is the hepatocyte (as in the case of autoimmune hepatitis (AIH)) or the bile duct cell (as in the case of primary biliary cirrhosis (PBC) or primary sclerosing cholangitis (PSC)). In between, there is a series of conditions sharing characteristics of both groups coined overlap syndromes with peculiar features as to clinical management. Regardless of the subgroup, all conditions eventually lead to liver cirrhosis and ultimately liver failure; however, progression rates vary widely and are likely determined by unknown genetic factors.

AUTOIMMUNE HEPATITIS

CLINICAL FEATURES AND DIAGNOSTIC CHALLENGE

AIH is a chronic disease of unknown etiology resulting from the immune-mediated destruction of hepatocytes secondary to a loss of immune tolerance against liver tissues. AIH major features¹ include striking female predominance, presence of hypergammaglobulinemia, significant association with the human leukocyte antigen (HLA) alleles DR3 and DR4, good clinical response to steroids and other immunosuppressive treatments, and detection of serum autoantibodies. In some cases, the diagnosis can be challenging due to the presence of confounding factors or features mimicking other conditions. For these reasons, a scoring system has been developed over the past years to account for all criteria that influence the likelihood of AIH diagnosis. The system, first introduced in 1992 and then modified in 1999, is a practical tool for clinical management and allows a high sensitivity and specificity in the diagnosis (Table 75.1). Factors taken into account in this system include sex, plasma biochemical variables, serum autoantibodies, liver histology, possible co-factors (drugs, alcohol, viruses), and response to medical treatment. The sum of all factors produces a score to be used for determining the likelihood of the AIH diagnosis either

KEY CONCEPTS

INFLAMMATORY HEPATOBIILIARY DISEASES

- >> An autoimmune pathogenesis is recognized for autoimmune hepatitis, implied for primary biliary cirrhosis, and suggested for primary sclerosing cholangitis
- >> In all cases, the etiology remains enigmatic, although the roles of genetic susceptibility and environmental factors are well established
- >> The diagnosis of autoimmune hepatitis, primary sclerosing cholangitis, and primary biliary cirrhosis is based on criteria comprising clinical, imaging, and histological factors
- >> Overlap syndromes can ensue between the diseases, possibly modifying the natural history and the therapy approach

prior to or after medical treatment; in particular, a score > 15 prior to therapy or > 17 after treatment is associated with a definite diagnosis of AIH while scores in the 10–15 (pre-treatment) or 12–17 (post-treatment) ranges characterize a probable case. The 1992 version of the scoring system allowed high sensitivity (89%) with a relatively low specificity, particularly in cases of chronic hepatitis C with autoimmune features (80%) or chronic cholestatic liver diseases (61%). The revised 1999 criteria appear to give a better distinction between PSC and AIH.

AIH is a rare disease estimated to have a prevalence of 170/million persons in Europe. As mentioned above, it affects women of any age more commonly than men, but the female-to-male ratio in AIH is lower compared to PBC. The onset is typically indolent and asymptomatic subjects diagnosed with AIH following a screening examination currently represent the majority of cases. On the other hand, if symptoms are present at diagnosis, these are nonspecific or secondary to end-stage liver disease (jaundice, pruritus, ascites, upper digestive bleeding).

Table 75.1 Revised 1999 diagnostic scoring system for autoimmune hepatitis (AIH)

Parameters/features	Score
Female sex	+2
Alkaline phosphatase (ALP)/aspartate aminotransferase (or alanine aminotransferase) ratio	
< 1.5	+2
1.5–3.0	0
> 3.0	–2
Serum globulins or immunoglobulin G above normal	
> 2.0	+3
1.5–2.0	+2
1.0–1.5	+1
< 1.0	0
Antinuclear antibody, SMA, or LKM1	
> 1:80	+3
1:80	+2
1:40	+1
< 1:40	0
AMA-positive	–4
Hepatitis virus markers	
Positive	–3
Negative	+3
Drug history	
Positive	–4
Negative	+1
Average alcohol intake	
< 25 g/day	+2
> 60 g/day	–2
Liver histology	
Interface hepatitis	+3
Predominantly lymphoplasmacytoid infiltrate	+1
Rosetting of liver cells	+1
None of the above	–5

Continued

Parameters/features	Score
Biliary changes	–3
Other changes	–3
Other autoimmune diseases	+2
Optional additional parameters	
Other defined autoantibodies	+2
Human leukocyte antigen (HLA) DR3 or DR4	+1
Response to therapy	
Complete	+2
Relapse	+3
A score > 15 or > 17 indicates a definite diagnosis of AIH pre- or post-treatment, respectively. On the other hand, scores between 10–15 and 12–17 indicate a probable diagnosis, pre- or post-therapy, respectively. AMA, anti-mitochondrial autoantibodies; LKM-1, anti-liver–kidney microsomal antibodies; SMA, anti-smooth-muscle antibodies.	

CLINICAL PEARLS**AUTOIMMUNE HEPATITIS**

- >> Autoimmune hepatitis is most commonly diagnosed in symptomless patients during routine blood work
- >> A scoring system is available to make the diagnosis of autoimmune hepatitis likely or definitive
- >> Several types of serum autoantibodies can be detected, in some cases with high specificity
- >> Three types are recognized based on clinical, epidemiological, and serological characteristics

BLOOD TESTS

Plasma biochemical evaluation commonly reveals a frank elevation of aminotransferases often accompanied by a cholestatic pattern (increased alkaline phosphatase, bilirubin). It is of note, however, that a ratio between the elevations of alkaline phosphatase and either transaminases higher than 3 is considered as indicative of chronic cholestatic disease and not of AIH, as also represented in the proposed scoring system. Furthermore, serum globulins, particularly of the γ type, are commonly increased in AIH cases regardless of the histological stage. Lastly and most importantly, serum autoantibodies are invariably positive (defined as titer = 1:80) in patients with AIH and allow a finer distinction of the three disease subtypes. In fact, type I is characterized by the presence of antinuclear (ANA) and/or anti-smooth-muscle (SMA, directed against actin) autoantibodies, type II by anti-liver–kidney microsomal antibodies (LKM-1, directed at cytochrome P450 2D6 or UDP-glucuronosyltransferases), and type III by autoantibodies

Table 75.2 Synopsis comparing clinical, serological, epidemiological, and genetic characteristics of autoimmune hepatitis (AIH) subtypes

Clinical features	Type 1	Type 2	Type 3
Diagnostic antibodies	SMA, ANA Anti-actin	Anti-LKM P450 IID6	Anti-soluble liver–kidney Ag, AK 8, CK18
Age (years)	Bimodal (10–20, 45–70)	Pediatric (2–14)	Adults (30–50)
Women (%)	78	89	90
Autoimmune comorbidity (%)	41	34	58
Gamma-globulin ↑	+++	+	++
Immunoglobulin A ↓	No	Occasional	No
Human leukocyte antigen (HLA) association	B8, DR3, DR4	B14, DR3, C4AQ0	Uncertain
Steroid response	+++	++	+++
Progression to cirrhosis (%)	45	82	75

Ag, antigens; ANA, antinuclear antibodies; Ig, immunoglobulin; LKM, anti-liver–kidney microsomal antibodies; SMA, anti-smooth-muscle antibodies.

against soluble liver antigens (SLA/LP). Apart from antibody patterns, these three subtypes also recognize other important clinical, epidemiological, and biochemical differences, as presented in Table 75.2.

LIVER HISTOLOGY

The role of liver histology in the management of AIH remains critical and all suspect cases should undergo a percutaneous liver biopsy. In fact, although no typical feature can be sufficient to prove the diagnosis, histology remains the gold standard for grading and staging, particularly to determine the response to therapy. Common findings include periportal hepatitis with lymphocyte and plasma cell infiltrate and piecemeal necrosis.¹ Fibrosis is usually observed and bridging necrosis ultimately indicates advanced disease evolving into frank cirrhosis. Importantly, the presence of granulomas, bile duct damage, or iron or copper accumulation should not be overlooked since these signs point towards other diagnoses. On the other hand, steatosis is a nonspecific finding that does not rule out AIH.

SERUM AUTOANTIBODIES

In 2004, the International Autoimmune Hepatitis Group established procedures and reference guidelines for more reliable serum autoantibody testing to overcome the lack of standardization.² In fact, routine tests for serum ANA, SMA, and LKM are critical in the diagnosis of AIH, as indicated by the diagnostic scoring system (Table 75.1). Other sets of autoantibodies should also be tested in suspected cases and include those against liver-cytosol type 1 (LC1), perinuclear anti-neutrophil cytoplasmic antibodies (pANCA), SLA/LP, and the asialoglycoprotein receptor. Finally, other less specific autoantibodies are also detected in a subgroup of patients, i.e., antibodies against cardiolipin, chromatin, and *Saccharomyces cerevisiae*, but are of limited clinical impact.

Antibodies to nuclear antigens

ANA were the first autoantibodies observed in AIH sera over 50 years ago and remain the most sensitive marker of AIH, most frequently producing a homogeneous or speckled pattern. The test is not specific for AIH, since ANA positivity is not uncommon in sera from patients with viral or other autoimmune liver diseases as well as in as many as 15% of healthy subjects. This latter percentage has recently been reduced by abandoning Hep2 cells as a substrate for indirect immunofluorescence, which remains the most widely used ANA screening method. The nature of AIH-associated ANA autoantigens is incompletely understood; these include centromeres, ribonucleoproteins, cyclin A, histones, and other antigens. Similar to most autoantibodies, ANA positivity, pattern, or titer does not reflect different AIH phenotypes nor can they predict the disease's natural history.

Antibodies to smooth-muscle antigen

Serum SMA react with different proteins (actin, tubulin, vimentin, desmin, cytokeratins) of the cytoskeletal components (microfilaments, microtubuli, intermediate filaments). Their presence characterizes both autoimmune (type 1 AIH, coeliac disease) and viral diseases (chronic hepatitis C, infectious mononucleosis). When detected at titers higher than 1:80, they are considered a sensitive marker for type 1 AIH, being found in up to 80% of cases. Within the spectrum of SMA, anti-actin antibodies are the most specific for the diagnosis of type 1 AIH. At present, immunomorphological techniques are still the gold standard for SMA testing; recently, however, new immunochemical tests with purified antigens have been demonstrated to be reliable. A pathogenic role for SMA in AIH has not been demonstrated and, to date, this is still a controversial topic. Finally, SMA-positive type 1 AIH sera also frequently react by counterimmunoelectrophoresis with an unknown antigen, provisionally called XR1, which is

present in the heterogeneous antigenic “cocktail” derived from the aqueous extract of rabbit thymus that is currently used to detect antibodies to extractable nuclear antigens.

Autoantibodies to liver–kidney microsomal antigens

Autoantibodies against microsomal proteins form a heterogeneous group and are associated with several immune-mediated diseases, including AIH and drug-induced hepatitis. Serum autoantibodies against LKM-1 are the main serological markers of type 2 AIH and recognize the proximal renal tubule and hepatocellular cytoplasm. The 50-kDa autoantigen was identified as the cytochrome P450 2D6 (CYP2D6). Interestingly, the sequence between amino acids 316 and 327, which is most likely exposed on the surface of the molecule, appears to be a region capable of differentiating LKM-1 activity in AIH and hepatitis C virus and may represent a key target for autoimmunity. The mechanisms of onset remain enigmatic and solid evidence of a causative role of hepatitis C virus cross-reactivity is still awaited. Similarly, the pathogenic role of anti-LKM-1 and their prognostic significance are debated, despite the development of type 2 AIH animal models following immunization with human CYP2D6 or with adenoviruses in mice transgenic for human CYP2D6. Finally, two other types of serum anti-LKM have been described in patients with ticrynafen-associated hepatitis (anti-LKM-2, directed against CYP2C9) and in 10% of patients with type 2 AIH (anti-LKM-3, directed against UGT1A), either alone or in combination with LKM-1 antibodies.

Autoantibodies to soluble liver antigen/liver pancreas antigen

Anti-SLA/LP antibodies are detectable by radioimmunoassay and enzyme-linked immunosorbent assay but not by immunofluorescence and are directed against different epitopes of a UGA tRNA suppressor. Serum anti-SLA/LP antibodies are occasionally found in patients with AIH who are negative for ANA, SMA, or anti-LKM and are cumulatively detected in 10–30% of cases of type 1 and type 2 AIH. Recent data indicate that anti-SLA/LP antibodies are also detectable in subgroups of pediatric patients with autoimmune cholangitis or adult patients with hepatitis C virus infection when tested with sensitive methods.

Antibodies to liver-cytosol type 1

Anti-LC1 antibodies are detected by indirect immunofluorescence in sera from up to 50% of patients with type 2 AIH and less frequently in type 1 AIH or chronic hepatitis C. Importantly, however, anti-LC1 are the only detectable markers in 10% of AIH cases.

The LC1 autoantigen is the liver formiminotransferase cyclodeaminase, an enzyme involved in folate metabolism. Interestingly, serum anti-LC1 antibodies correlate with AIH severity and progression.

Other autoantibodies

Antibodies to the asialoglycoprotein receptor are observed in up to 90% of all patients with AIH and often coexist with other autoantibodies while lacking specificity for the disease. Similar to anti-LC1, however, anti-asialoglycoprotein titers are associated with a more florid inflammatory disease activity and may monitor treatment response.

Antibodies to neutrophil cytoplasmic antigens (pANCA) can be detected by indirect immunofluorescence in sera from patients with type 1 AIH but also in a subgroup of patients with PSC or chronic viral hepatitis.

PATHOGENESIS

Similar to most autoimmune diseases, the current hypothesis states that environmental factors trigger autoimmunity onset in genetically susceptible individuals. Several microorganisms, particularly viruses, have been suggested as triggers but sound evidence is still awaited. The proposed mechanism is based on molecular mimicry between infectious agent epitopes and human liver antigens. There has been evidence implicating measles virus, cytomegalovirus, and Epstein–Barr virus as initiators of the disease while the most solid data were obtained with hepatitis C virus.³

From a genetic standpoint, AIH is considered a complex disease not following a strictly hereditary pattern.⁴ In fact, conclusive data of a single genetic locus causing AIH onset have not been obtained and multiple genes are likely to contribute to disease susceptibility. Recently developed technologies such as the genome-wide scan appear promising in unraveling the genetic mysteries of AIH.

Most evidence in AIH genetics comes from the study of major histocompatibility complex (MHC) alleles, critical molecules in the T-cell recognition process (Chapter 7). Data from Caucasian patients in northern Europe and the USA reported an association with HLA DRB1*0301 and DRB*0401 although most reported associations appear to be limited to specific geographical areas or ethnicities. Nevertheless, the association of AIH with DR3 and DR4 alleles is solid to the point of being included in the diagnostic scoring system currently in use. The scenario is further complicated by the possibility that different environmental factors trigger AIH in different areas. HLA alleles associated with AIH not only confer susceptibility towards AIH but also appear to influence the course of the disease. Most strikingly, patients with DRB1*0301 are younger at disease onset and have a lower frequency of response to treatment. HLA DR3 is further associated with a lower probability of remission, manifesting more frequent relapses and need for liver transplantation. Furthermore, associations have also been reported between AIH and tumor necrosis factor- α and carbonic anhydrase gene polymorphisms, although these genes might not represent primary susceptibility genes but rather markers of MHC associations. Outside the MHC cluster, polymorphisms of genes involved in the regulation of immune responses have been investigated, leading to inconclusive data. These include the cytotoxic T-lymphocyte antigen 4 (CTLA-4), cytokines, vitamin D receptor, CD45, and Fas receptor.

NATURAL HISTORY

Data on the natural course of AIH are limited, particularly due to the paucity of clinical trials during the past decades⁵ when hepatitis C became manifest as a common confounding factor significantly influencing the disease progression. Accordingly, older studies reported that AIH had a very poor prognosis and 5- and 10-year survival rates of 50% and 10% without treatment while immunosuppressants could significantly improve survival to 10-year rates as high as 90%. At the time of diagnosis, approximately 30% of adult patients have histological evidence of cirrhosis; when appropriately treated, however, only a small number of patients develop cirrhosis during follow-up if an anti-inflammatory response is achieved.

Nevertheless, having cirrhosis at presentation significantly increases the risk of liver-related death or the need for liver transplantation.

The scenarios are different when pediatric or elderly cases are studied. In fact, almost 50% of children with AIH already manifest cirrhosis at diagnosis and the majority of patients require long-term immunosuppressive treatment until adulthood. In elderly patients a more severe initial histology grade should be expected, alongside a similar response rate to immunosuppression. It is still debated if these patients should be treated with higher or lower doses of steroids. Beside age at presentation, race also modifies disease progression data. In fact, cirrhosis is more frequent at younger age in African-American patients with AIH compared to Caucasian subjects from the same areas.

The occurrence of hepatocellular carcinoma in patients with AIH is a rare event and only develops in long-standing cirrhosis. In the absence of solid data on large numbers of cases, primary liver neoplasia incidence should be regarded as similar to other nonviral cases of cirrhosis.

THERAPY

Different from the other autoimmune liver diseases described herein, immunosuppressants are the treatments of choice for AIH, based on the good response in terms of biochemistry, histology, and survival.⁶ Corticosteroids (prednisone), as monotherapy or in combination with azathioprine, are the first line of treatment and should be started in patients with aminotransferase levels > 5 times the upper normal limit or histological evidence of bridging or multilobular necrosis. Prednisone and azathioprine appear equally effective. Treatment follows guidelines (Table 75.3) but tailored schedules are encouraged in selected cases. In asymptomatic patients with milder presentation, the opportunity to treat is still a matter of debate since the survival of these patients without treatment is similar to the overall AIH population.⁷ Nevertheless, a close follow-up is required in these patients since symptoms develop in 25% of cases. The goal of a biochemical and histological resolution of inflammation as well

as the clinical remission of symptoms is observed in up to 80% of patients treated with steroids within the first 3 years, most commonly during the first few months. It should be noted, however, that subgroups of patients manifest disease progression (approximately 10%) or are intolerant to standard therapy (13%). Relapses following therapy discontinuation are common since only 20% of patients remain in sustained remission. Second-choice therapies include cyclosporine A, tacrolimus, cyclophosphamide, mercaptopurine, mycophenolate mofetil, or deflazacort, thus far tested in small populations of patients. Ursodeoxycholic acid (UDCA) is a well-tolerated drug; its efficacy in AIH therapy or in combination with immunosuppressive therapy is still not established, particularly in terms of survival or histological improvement. Finally, patients with end-stage liver disease or fulminant presentation who do not respond to immunosuppressive therapy should be promptly considered for liver transplantation. Patients with AIH undergoing liver transplant have overall 5- and 10-year survival rates of 90% and 75%, respectively, although disease recurrence is common.

PRIMARY BILIARY CIRRHOSIS

PBC is a chronic cholestatic liver disease of unknown etiology characterized by high-titer serum anti-mitochondrial autoantibodies (AMA) and an autoimmune-mediated destruction of the small and medium-sized intrahepatic bile ducts. It affects women more frequently than men, with a female-to-male ratio of 9:1, the average age at diagnosis is within the 5th and 6th decades of life, and it presents a geographical pattern of prevalence. Table 75.4 illustrates the epidemiological data currently available for PBC. Sporadic cases of PBC onset in pediatric ages have recently been reported. The diagnosis of PBC is based on the presence of two out of three internationally accepted criteria, i.e., detectable serum AMA (titer > 1:40), increased enzymes indicating cholestasis (i.e., alkaline phosphatase) for longer than 6 months, and a compatible or diagnostic liver histology. The classification proposed to indicate a definite diagnosis only when all criteria are met may

Table 75.3 Treatment guidelines for autoimmune hepatitis

Therapeutic stages	Single-drug regimen	Combination regimen
Induction therapy		
Week 1	40–60 mg prednisone/day ^a	40–60 mg prednisone/day + 1–2 mg azathioprine/kg body weight
Week 2	40 mg prednisone/day	15 mg prednisone/day + 1–2 mg azathioprine/kg body weight
Week 3	30 mg prednisone/day	15 mg prednisone/day + 1–2 mg azathioprine/kg body weight
Week 4	Taper down 5 mg every week, until maintenance therapy	15 mg prednisone/day + 1–2 mg azathioprine/kg body weight
<i>Maintenance therapy</i>	5–15 mg prednisone/day are common	10 mg prednisone/day + 1–2 mg azathioprine/kg body weight dosages <i>Alternative option:</i> 2 mg/kg azathioprine as monotherapy

CLINICAL PEARLS

PRIMARY BILIARY CIRRHOSIS

- >> Primary biliary cirrhosis is a rare disease, affecting middle-aged women more commonly than men
- >> Genetic factors are critical, yet not well defined, in the pathogenesis of the disease; environmental factors are important, possibly infectious or chemical
- >> The serum hallmark is serum anti-mitochondrial antibodies (AMA), found in >90% of cases
- >> At presentation, patients most commonly manifest early stages and have nonspecific symptoms, such as fatigue or pruritus

be too narrow as, for example, patients lacking serum AMA appear to follow a similar natural history when compared to their AMA-positive counterparts.⁸ Although it remains critical for the assessment of the histological stage, the issue of whether a liver biopsy is needed for the diagnosis of PBC is still highly debated. Currently, performing a liver biopsy seems not to be indicated when the other two diagnostic criteria are met. In a large number of cases (20–60%) the diagnosis of PBC is established in the absence of symptoms indicating a liver condition or cholestasis, and the proportion of asymptomatic cases at diagnosis has been increasing since the first series were reported.

CLINICAL FEATURES

Symptoms most commonly accompanying PBC at presentation are classically defined as fatigue and pruritus while physical findings may include skin hyperpigmentation, hepatosplenomegaly, and (rarely) xanthelasmas. End-stage symptoms are those of all types of liver cirrhosis, including ascites, jaundice, hepatic encephalopathy, and upper digestive bleeding. *Fatigue* is an incompletely defined, nonspecific symptom that affects up to 70% of patients with PBC and that is often overlooked, particularly in middle-aged women. Importantly, the severity of fatigue is independent of the stage of PBC or its other features (pruritus or severe cholestasis), nor does it depend on psychiatric factors. No medical treatment has been shown to be effective in alleviating this symptom, although fatigue has never been included as an endpoint in any of the large controlled clinical trials.

As many as 70% of patients with PBC and jaundice suffer from *pruritus*. Longitudinal data show that the vast majority of patients will eventually experience this symptom during their lifetime; pruritus might long precede jaundice onset. Typically, pruritus worsens at night, following contact with wool, or in warm climates. The bases of PBC-associated pruritus are not clear and two hypotheses have been proposed: serum bile acid retention secondary to chronic cholestasis or amplified release of endogenous opioids. Treatment of pruritus can be challenging for the clinician. The use of cholestyramine (4 g two or three times a day) ameliorates pruritus. In cases poorly responsive to resins, rifampicin has been used to achieve rapid symptom relief; its prolonged use, however, should be avoided. Based on the opioid theory of pruritus, treatment with opiate antagonists such as naltrexone (50 mg/day) is currently being used, with limited adverse effects. The recently

proposed use of sertraline is encouraged by promising preliminary data but warrants further evaluation.

Portal hypertension is frequently found in patients with PBC and, importantly, does not imply the presence of liver cirrhosis. Over half of untreated patients eventually develop portal hypertension over a 4-year period. The prevention and treatment of PBC-associated portal hypertension are not different from other chronic liver diseases.

Although there are conflicting data, it appears that accelerated bone loss accompanies long-standing cholestasis in PBC compared to sex- and age-matched healthy individuals. It has been coined *metabolic bone disease* secondary to reduced bone deposition. Current treatment of bone loss includes oral calcium supplementation, weight-bearing activity, and oral vitamin D replacement, if deficiency is found. Postmenopausal hormone replacement therapy should be considered but jaundice and other signs of liver failure should be evaluated during the first months of treatment. Efficacy and safety of other treatments are being evaluated.

Hyperlipidemia is common in up to 85% of patients with PBC and both serum cholesterol and triglyceride high levels can be observed. Interestingly, however, such alterations are not accompanied by a proportionally increased incidence of cardiovascular events or atherosclerosis and do not correlate with disease stage. Treatment with bile acid helps reduce blood lipids levels via unknown mechanisms.

Comorbidity is an important feature of PBC. Various disorders, particularly other autoimmune syndromes, are associated with PBC at various degrees. Our epidemiological study of 1032 patients with PBC has demonstrated that one-third of cases are also affected by another autoimmune disease, most commonly Sjögren's syndrome, Raynaud's phenomenon, autoimmune thyroid disease, scleroderma, and systemic lupus erythematosus, while the prevalence of rheumatoid arthritis did not differ from controls.⁹ Interestingly, recent data demonstrated that patients affected by both PBC and scleroderma manifest a less aggressive liver disease, thus suggesting an active interaction between the two conditions. Similarly to other types of cirrhosis, end-stage PBC can be complicated by the occurrence of *hepatocellular carcinoma* and patients with intense nodular liver structure at ultrasound should be monitored by computed tomography. Importantly, PBC does not associate with cholangiocarcinoma (CCA) or breast cancer.

BLOOD TESTS

At presentation, PBC is suspected if a biochemical cholestatic pattern represented by increased plasma alkaline phosphatase or γ -glutamyltransferase is present. Such increase is typically not accompanied by an increase of similar magnitude in plasma aminotransferase levels. Serum immunoglobulin M levels are typically elevated in PBC cases without being correlated with AMA titers or levels of other Ig subtypes. Data suggest that this phenomenon might be secondary to an aberrant response of patients' memory B cells to bacterial stimuli¹⁰ but its clinical significance remains enigmatic. Once cirrhosis has developed, biochemical alterations are similar to other types of cirrhosis.

LIVER HISTOLOGY

According to the classification of Ludwig et al.,¹¹ histology identifies four PBC stages. Stage I manifests with portal tract inflammation with predominantly lymphoplasmacytic infiltrates, resulting in vanishing

septal and interlobular bile ducts (diameter < 100 µm). At this stage, bile duct obliteration and granulomas (possibly found at all stages) are strongly suggestive of PBC. In stage II a periportal inflammatory infiltrate is observed and signs of cholangitis, granulomas, and florid proliferation of ductules are typical. Stage III demonstrates septal or bridging fibrosis, with ductopenia (over half of the visible interlobular bile ducts having vanished) and copper deposition in periportal and

paraseptal hepatocytes can be seen. Stage IV corresponds to frank cirrhosis. The observation of eosinophils in the portal tract is a specific finding in PBC histology. Finally, the possibility of a sampling error should be considered when evaluating histology in PBC and, in case of variable staging within one biopsy, the highest stage should be accepted. [Figure 75.1](#) illustrates the histological findings in representative cases of early PBC.

SERUM AUTOANTIBODIES

Anti-mitochondrial antibodies

AMA are highly specific for PBC and can be detected in nearly 100% of patients when sensitive diagnostic methodologies based on recombinant antigens are used.¹² In most clinical settings, however, indirect immunofluorescence techniques are used for initial screening of cases and might provide falsely positive or negative results. AMA are directed against components of the 2-oxoacid dehydrogenase (2-OADC) family of enzymes within the mitochondrial respiratory chain,¹³ most frequently the E2 and

E3-binding protein (E3BP) components of the pyruvate dehydrogenase complex and the E2 components of the 2-oxo glutarate dehydrogenase and branched-chain 2-oxo acid dehydrogenase complexes. In all three antigens epitopes contain the motif DKA, with lipoic acid covalently bound to the lysine (K) residue. The role of lipoic acid in epitope recognition by AMA is unclear. The pathogenic role of AMA is debatable, since no clinical correlation can be found and animal models developing serum AMA do not develop PBC-like liver lesions.

Antinuclear antibodies

As many as 50% of patients with PBC have detectable serum ANA, most commonly producing 'nuclear rim' or 'multiple nuclear dots' patterns. The pattern is based on the recognition by the autoantibodies of gp210 and nucleoporin 62 (within the nuclear pore complex) and Sp100 and promyelocytic leukemia protein (PML) (possibly also cross-reacting with small ubiquitin-like modifiers, SUMO), respectively.¹⁴ ANA-positive patients are more frequently AMA-negative, possibly because of the lack of a masking effect of these latter antibodies in such sera. The pathogenic role of ANA in PBC remains enigmatic, although cross-sectional and longitudinal data demonstrate an association between ANA positivity and a worse prognosis. Finally, patients with PBC and limited systemic sclerosis have detectable serum anti-centromere antibodies in 10–15% of cases.

PATHOGENESIS

Several clinical and experimental findings strongly imply an autoimmune pathogenesis for PBC while two components are necessary for disease onset: a permissive genetic background and an environmental trigger.

Genetics

PBC is more frequent in relatives of affected individuals and the term 'familial PBC' has been coined to indicate families that have more than one case. Our data indicate 6% of cases have a first-degree relative that is also affected.⁹ More importantly, the concordance rate observed among monozygotic twins for PBC is 63%, amongst the highest reported in autoimmunity, reinforcing the idea of an important role of genetics in disease susceptibility.¹⁵ Several association studies have attempted to identify genes associated with PBC although no family study of genetic linkage has been performed. Associations are often not applicable to all populations but suggest that a multi-hit genetic model seems to apply to PBC, with different genetic variants conferring susceptibility (first hit) and others influencing disease progression (second hit). The study of the variants of MHC (including type I, II, and III loci) have produced associations that are often weak or limited to specific geographical areas.¹⁴ Similar findings were also reported from the study of the genetic variants of immunomodulatory molecules (such as chemokines and their receptors), enzymes producing vasoactive compounds, and bile acid transporters that have recently been extensively reviewed elsewhere.¹⁶ Recently, Invernizzi and colleagues reported an age-dependent enhanced monosomy X in peripheral white blood cells of women with PBC,¹⁷ thus suggesting that PBC might ensue from a polygenic model with an X-linked major locus of susceptibility in which genes escaping inactivation are the major candidates. On the other hand, it can also be hypothesized that susceptibility to PBC is the result of a multigenic complex inheritance model where Y-linked genes might exert a protective role.

Environmental factors

Although genetics should be regarded as the major determinant in susceptibility to PBC, several other factors have been proposed. Our epidemiological study has demonstrated that a high risk of developing PBC is associated with a positive family history for PBC, a history of urinary or vaginal infections, comorbidity with other autoimmune diseases, lifestyle factors, such as smoking, and previous pregnancies (Table 75.5). Furthermore, we observed that the frequent use of nail polish also slightly increased the risk of having PBC. Experimental studies have focused on two main classes of agents possibly triggering PBC: infectious (bacteria and viruses) and chemical (xenobiotics). Most evidence has been reported for *Escherichia coli*, while contrasting data have been obtained on the role of *Chlamydia pneumoniae*. Finally, we have provided experimental evidence suggesting that *Novosphingobium aromaticivorans*, a ubiquitous xenobiotic-metabolizing Gram-negative bacterium, is the best candidate yet for the induction of PBC.¹⁸ Figure 75.2 illustrates our bacterial theory. A retroviral hypothesis has also been proposed for PBC but direct proof is still awaited after data were not reproduced. Xenobiotics are foreign compounds that may either alter or complex to defined self or non-self proteins, inducing a change in the molecular structure of the native protein sufficient to induce an immune response. Such immune responses may then result in the cross-recognition of the self form, which could in

turn perpetuate the immune response, thus leading to chronic autoimmunity. Interestingly, most xenobiotics are metabolized in the liver, thereby increasing the potential for liver-specific alteration of proteins. Data from our laboratory at UC Davis demonstrate that certain chemical compounds can induce AMA or are in fact recognized by patients' sera with higher affinity compared to self proteins^{19,20} and that specific ones are found in common-use products.²¹

NATURAL HISTORY

The progression of PBC varies widely, as represented by patients remaining asymptomatic and others reaching liver failure at young ages. The factors influencing the severity and progression of the disease are largely unknown, although data seem to indicate that genetic factors other than those inducing the disease ('second hit') might play a role. In general terms, the natural history of the disease is into three time periods preceding liver failure, i.e., asymptomatic, symptomatic, and pre liver failure. The duration of these periods can vary significantly but we note that the first step might last for decades, while the third is usually very rapid. The diagnosis of PBC is most commonly made within the first stage; patients presenting with symptoms or advanced disease are currently less frequent compared to older reports.

Having symptoms at presentation is considered the major factor determining survival rates of patients with PBC. In fact, symptomless PBC is accompanied by 10-year survival rates similar to the general population. On the other hand, 67% of precirrhotic patients will develop liver cirrhosis over a 7-year observation period while 70% of asymptomatic patients will develop symptoms. Accordingly, more recent regression models indicate that asymptomatic patients with PBC have significantly lower survival than the general population. Based on the conflicting data, it has been hypothesized that survival rates of asymptomatic patients with PBC are shorter than the general population if symptoms develop during follow-up.²² An additional confounding factor is provided by the rate of non-liver-related deaths that appears to cause the reduced survival of asymptomatic patients.²³ Further studies on large populations and longer follow-up periods are clearly warranted.

Patients with symptomatic PBC show a more rapid progression to late-stage disease and a worse prognosis than their asymptomatic counterparts with survival time among symptomatic subjects within 6–10 years.²⁴ Older age at diagnosis and signs of advanced disease (clinical, histological, or biochemical) are associated with a worse prognosis. The establishment of accurate prognostic models to predict survival in patients with PBC is of obvious importance in the clinical practice. The model based on the Mayo score is the only validated and most widely utilized²⁵; it is calculated based on clinical (age, presence of ascites) and biochemical variables as represented by cholestasis (bilirubin levels) and liver function (prothrombin time, albumin). We submit that this model is a static representation of a dynamic entity and has a lower accuracy for patients with early disease. Most recently, Invernizzi and colleagues reported that PBC-specific serum ANA, albeit found in a minority of patients, can predict a more aggressive disease, as suggested by longitudinal data collected during long follow-up periods.¹⁴

THERAPY

The only approved treatment for PBC is the hydrophilic bile acid UDCA. The mechanism of action of UDCA in PBC is incompletely understood but it has been hypothesized that it is based on

Fig. 75.2 Representation of the proposed theory on the etiopathogenesis of primary biliary cirrhosis based on the suggested role of *Novosphingobium aromaticivorans* in combination with individual susceptibility and environmental factors. The bacterium enters the mucosal system and its lipoylated proteins (Novo) are modified by xenobiotics, thus creating immunoreactive molecules. Modified proteins are then processed by antigen-presenting cells (APC) in the mucosa, thus activating autoreactive T and B cells. While T cells exert a cytopathic effect directly and/or recruit additional lymphocytes, B cells secrete anti-mitochondrial autoantibodies (AMA) of the immunoglobulin G (IgG) and IgA isotype. IgA enter the lumen of biliary epithelial cells (BECs) by transcytosis and then react with molecules mimicking pyruvate dehydrogenase E2 (PDC-E2), thus initiating apoptosis. The intact PDC-E2 liberated from apoptotic cells forms immune complexes with circulating AMA IgG. Such immune complexes, the enhanced apoptosis, the direct cytopathic effect of T cells, and possibly AMA eventually lead to the appearance of the histological signs of primary biliary cirrhosis, i.e., chronic nonsuppurative cholangitis.

different factors, including modification of the bile acid pool, reduction in proinflammatory cytokines, effects on apoptosis and on vasoactive mediators.²⁶ Doses ranging from 13 to 15 mg/kg of UDCA are currently used and lead to optimum bile enrichment. Accordingly, a meta-analysis demonstrated that an increased survival is only obtained when a dose > 13 mg/kg is prescribed,²⁷ despite the fact that a complete biochemical response to UDCA is achieved in approximately 40% of treated patients. Immunosuppressive drugs have also been used in PBC with poor efficacy, including corticosteroids, azathioprine, cyclosporine, methotrexate, penicillamine, and colchicine. Their use is currently encouraged only in combination with UDCA in selected cases (i.e., when features of AIH are found). Definitive data are still awaited on the efficacy of UDCA plus bezafibrate, mycophenolate mofetil, budesonide, and tamoxifen. Liver transplantation is the ultimate treatment for end-stage PBC, with survival rates of 92% and 85% at 1 and 5 years after transplant, respectively. Recurrence is common and its rates seem to be influenced by certain immunosuppressive regimens, while the use of UDCA for recurrence is safe and recommended.

PRIMARY SCLEROSING CHOLANGITIS

PSC is a progressive cholestatic liver disease of unknown etiology presenting with autoimmune features and associated with significant morbidity and mortality. Different from PBC, PSC can affect all tracts of the biliary tree, including the extrahepatic bile ducts. Epidemiological data indicate that annual incidence rates are not increasing over time despite earlier ages at diagnosis and, possibly, longer survival, similar to what was observed in PBC. Recent data from the northern USA (Olmstead County, MN) reported a disease prevalence of 20.9 per 100 000 men and 6.3 per 100 000 women.²⁸ In fact, different from the vast majority of autoimmune diseases, PSC is more commonly diagnosed in men, with a female-to-male ratio estimated as 1:2.

CLINICAL FEATURES

PSC is currently diagnosed most commonly in the absence of symptoms and during routine blood tests in healthy individuals or patients with inflammatory bowel disease (IBD). In fact, PSC is strongly associated with

IBD, particularly ulcerative colitis (UC) with prevalence rates as high as 4%. Conversely, patients with PSC are affected by IBD in >75% of cases (more commonly UC). The other important association is with CCA, which is found in 7–13% of patients with PSC. At early stages, PSC symptoms are generally nonspecific and include abdominal pain, jaundice, and fever in the case of bacterial cholangitis. The management of symptoms, which also include pruritus, bone density reduction, and fatigue, is similar to that described for PBC. At more advanced stages, symptoms include those of all types of decompensated cirrhosis or neoplasia. Commonly, PSC is further complicated by episodic bacterial cholangitis favored by biliary strictures. Lastly, subgroups of patients manifest the “small-duct” variant or overlap syndrome.

DIAGNOSIS

PSC is characteristically accompanied by a biochemical cholestatic pattern, as represented by elevated serum alkaline phosphatase and γ -glutamyltransferase, while tests of liver function are normal until late stages. Autoantibodies are of limited use in the diagnosis of PSC due to low sensitivity and specificity. A variable percentage of patients (as low as 33%) have detectable serum atypical p-ANCA, which can also be found in patients with AIH or IBD without PSC. More useful in the diagnosis of PSC are the imaging techniques that demonstrate strictured and dilated tracts within the intrahepatic or extrahepatic bile ducts. Among the imaging approaches in use, endoscopic retrograde cholangiopancreatography (ERCP) and magnetic resonance cholangiopancreatography (MRCP) are currently considered equal for sensitivity but their results are influenced by the operator's skills and experience. Liver histology is crucial in establishing the diagnosis in the case of small-duct PSC (typically characterized by the absence of ERCP or MRCP alterations) or PSC-AIH overlap syndrome.

LIVER HISTOLOGY

Although not necessary for establishing the diagnosis, liver histology is essential for the staging of PSC or when the small-duct variant, an overlap syndrome, or CCA is suspected. The histological picture varies widely, from minimal alterations to cirrhosis with portal inflammation, concentric ‘onion-skin’ periductal fibrosis, and periportal fibrosis developing into septal and bridging necrosis. Similar to PBC, sampling errors should be considered in the liver sample collection. Histological findings are only diagnostic in one-third of patients. **Figure 75.3** illustrates the histological findings in two representative cases of early and advanced PSC.

INFLAMMATORY BOWEL DISEASE

As mentioned above, the majority of patients with PSC are also affected by IBD, often at asymptomatic stages.²⁹ Alongside the varying genetic background for IBD in different areas, the prevalence of IBD in patients with PSC changes in various part of the world. Accordingly, asymptomatic patients with PSC should undergo endoscopic evaluation with appropriate histological sampling. When IBD is found in this setting, IBD symptoms can ensue several years after diagnosis. Importantly, UC in patients with PSC is clinically different from UC without PSC in that it is often quiescent and rectum-sparing. Furthermore, PSC comorbidity in UC increases the risk of colon dysplasia or carcinoma compared to UC alone.

PATHOGENESIS

The etiopathogenesis of PSC is unknown, despite growing evidence that (auto)immune-mediated mechanisms play a role.³⁰ This is indicated by the association with IBD in the majority of patients, the presence of serum autoantibodies, and the reported HLA susceptibility associations. It has been hypothesized that PSC is either an atypical autoimmune disease or an immune-mediated inflammatory disease. From a genetic standpoint, PSC occurs in susceptible individuals, as indicated by several association studies, particularly with HLA haplotypes. Family and twin studies are not available for PSC. Experimental insights into the disease pathogenesis have demonstrated a multistep pathway where innate immunity and microorganisms (possibly derived from an IBD-affected gut) play a role. In particular, cholangiocytes are first activated by bacterial stimuli in the

presence of gut-specific chemokines and endothelial cell adhesion molecules in the environment. Further, gut-primed T cells migrate into the portal tracts and peribiliary spaces where focal lesions subsequently appear. Finally, chronic inflammation and progressive fibrosis of the biliary epithelium lead to chronic cholestasis secondary to vanishing bile ducts and ultimately to biliary cirrhosis.

NATURAL HISTORY

Cumulatively, data on the natural history of PSC indicate that the median timespan from diagnosis to liver-related death or liver transplantation can be estimated at 18 years.³¹ It is still debated whether medical treatment with UDCA in fact produces a longer survival. The prognosis is clearly influenced by the possible onset of CCA. In most cases, an early diagnosis of CCA is problematic since its clinical presentation is not distinguishable from benign dominant biliary strictures and cytology is not 100% sensitive in the diagnosis of the neoplasia.³² Similar to forms not associated with PSC, the prognosis of PSC-related CCA at 1 year is extremely poor, with the exception of selected patients undergoing liver transplantation.

Another important distinction in predicting the natural history is small-duct PSC. In fact, the clinical course of this subgroup of patients is relatively benign and only a minority (12%) of patients progresses to develop classical PSC.³³ Importantly, no CCA occurrence was reported in these cases, although IBD comorbidity was equally common (with possibly a higher representation of Crohn's disease), compared to classical PSC.

THERAPY

The treatment of PSC includes medical and endoscopic measures, as well as liver transplantation.³⁴ Most clinical trials in PSC have investigated the effects of UDCA, with conflicting results (Table 75.6). Taken together, the available evidence suggests that UDCA is not proven to produce a substantial change in the course of PSC, despite remaining the most prescribed drug. However, it appears that high-dose UDCA might reduce the rate of progression³⁵ and might prevent the development of colon cancer in patients with PSC and UC. Endoscopic measures are indicated to treat complicated PSC through the opening of short- and long-segment stenoses of the common bile duct and short-segment stenoses of the hepatic ducts near to the bifurcation.³⁶ The treatment can be repeated over time once restenoses ensue and resulting survival rates are higher compared to patients not treated endoscopically. Finally, PSC represents an important indication for liver transplantation since patients are commonly younger compared to other autoimmune liver diseases.³⁷ Indication is made in the absence of biliary neoplasias (ruled out by bile duct brushing) and timing is challenging due to the variable disease course. Survival rates at 1 year are approximately 90% and are only slightly lower in patients in whom CCA is diagnosed on the explanted liver. Recurrence of disease is common and affects 20–40% of transplanted patients during prolonged follow-up.

AUTOIMMUNE CHOLANGITIS

The term 'autoimmune cholangitis' was first introduced to indicate AMA-negative PBC, possibly with serum ANA.³⁸ However, more recently a broader significance has been suggested to include: (1) serum ANA and/or SMA positivity and/or hypergammaglobulinemia; (2) serum

KEY CONCEPTS

PRIMARY SCLEROSING CHOLANGITIS

- >> Primary sclerosing cholangitis is a cholestatic liver disease of unknown etiology that is more common in men
- >> It might affect any section of the biliary tree, usually producing strictures and dilation
- >> Primary sclerosing cholangitis is significantly associated with inflammatory bowel diseases, particularly ulcerative colitis in an often indolent form
- >> An increased risk of cholangiocarcinoma is present and the diagnosis is often challenging

THERAPEUTIC PRINCIPLES

INFLAMMATORY HEPATOBILIARY DISEASES

- >> Despite common putative pathological mechanisms (i.e., autoimmunity), the treatment of early stages of autoimmune hepatitis (AIH), primary biliary cirrhosis (PBC), and primary sclerosing cholangitis (PSC) differs significantly
- >> Immunosuppressants (steroids, azathioprine) are the only effective treatments for AIH
- >> Ursodeoxycholic acid (13–15 mg/kg per day) is the only effective treatment for PBC
- >> Ursodeoxycholic acid at high doses (> 20 mg/kg per day) for PSC might influence disease progression while endoscopic treatments may ameliorate cholestasis
- >> Once liver cirrhosis ensues, treatment of complications (ascites, digestive bleeding) does not differ from other types of cirrhosis
- >> Liver transplantation is the only effective treatment for all three conditions, with good survival rates; relapses are common

AMA negativity by immunofluorescence; (3) biochemical and/or histological features of cholestatic and hepatocellular injury; and (4) exclusion of chronic viral, metabolic, or toxic liver disease.³⁹ This definition possibly includes PBC with atypical presentation, small-duct PSC, idiopathic adulthood ductopenia, and transitional stages of the classic diseases. Consensus is still awaited on this issue.

OVERLAP SYNDROMES

It is currently estimated that as many as 18% of patients with autoimmune liver disease also manifest features on a second autoimmune liver disease. These patients are considered to have overlap syndromes.⁴⁰ Patients with overlap syndromes usually present with both hepatocellular and cholangiocellular injury with biochemical and histological features of AIH and PBC or PSC. When not treated, these patients show a progressive course toward liver cirrhosis and failure. More specifically, AIH–PBC overlap syndrome is found in 10% of adults with AIH or PBC and AIH–PSC

overlap syndromes in 6–8% of children, adolescents, and young adults with AIH or PSC. Besides overlaps, transitions are also possible in rare cases from PBC to AIH, AIH to PBC, or AIH to PSC. The pathogenesis of overlap syndromes is poorly understood, and few data are available regarding the clinical characteristics and outcome of these syndromes. Thus, the clinical management of overlap syndromes is based on single diseases while medical treatment is empiric. Therefore, UDCA is used for chronic cholestasis and immunosuppressants (steroids and azathioprine) for AIH, while liver transplantation is indicated for end-stage disease.

CONCLUDING REMARKS

As indicated by the discussed evidence, several aspects of inflammatory hepatobiliary diseases remain enigmatic. Moreover, it appears that PBC, PSC, and AIH share limited features and should be considered as single diseases in clinical practice as well as in bench research. Specifically, medical treatment of those diseases has substantial differences in response and outcomes. Finally, while it appears straightforward in many cases, the diagnosis of these conditions is often challenging. Overlap syndromes and antibody-negative forms are commonly difficult to define and can only be resolved through a collaborative effort by radiologists, pathologists, and hepatologists.

Lymphoid leukemias

Moshe E. Gatt, Dina Ben-Yehuda, Shai Izraeli

76

The leukemias are a group of malignant clonal diseases arising in the bone marrow, each of which is characterized by a specific set of clinical and laboratory features. This chapter focuses on the two most common lymphoid leukemias, acute lymphoblastic leukemia (ALL) and chronic lymphocytic leukemia (CLL). ALL is the most common leukemia of lymphoid precursors. CLL consists of a clonal accumulation of mature lymphoid cells and is the most common type of leukemia in adults. Special emphasis is given to immunological aspects of both diseases.

■ ACUTE LYMPHOBLASTIC LEUKEMIA ■

ALL is characterized by the clonal proliferation and accumulation of malignant lymphoid progenitors. ALL is typically viewed as a developmental disease of the lymphoid system. Indeed, it is believed that most of childhood ALL arise as a 'developmental accident' during normal fetal lymphopoiesis.¹ Studies of chromosomal translocations in ALL cells have identified key genes involved in normal lympho- and hematopoiesis. Conversely, basic studies of the development of the immune system and the immune receptors have provided important tools for the diagnosis and management of ALL. These achievements in basic and clinical research have led to the remarkable transformation of ALL from what was a uniformly fatal disease several decades ago to a disease that is curable in more than 80% of children. Unfortunately, at present adults do not fare as well.²⁻⁴

EPIDEMIOLOGY AND ETIOLOGY

ALL is the most common malignancy of childhood. One in every 2000 children will develop leukemia by 15 years of age. In contrast ALL accounts for fewer than 20% of leukemias in adults. In developed countries, incidence peaks at 2-5 years of age (to about 55 per million), remains low during later childhood, adolescence, and young adulthood (fewer than 10 per million), and then rises again in individuals older than 65 years of age. In all age groups, males tend to be affected more often than females. The low age peak is characteristic of affluent societies, and

the higher rate of childhood ALL in whites than blacks and in northern America and Europe compared with Asia and Africa has been attributed to socioeconomic factors.⁵

Most ALLs are sporadic. Fewer than 5% are associated with hereditary or constitutional syndromes. Children with Down syndrome have about 20-fold increased risk of ALL. This higher risk may reflect the leukemogenic role of chromosome 21, as extra copies of chromosome 21 are frequently observed in leukemic blasts of sporadic ALL.⁶ Other diseases associated with increased risk are inherited genomic instability syndromes such as ataxia-telangiectasia, Bloom syndrome and Li-Fraumeni syndrome. ALL is also more common in patients with other congenital immunodeficiencies, such as X-linked agammaglobulinemia, immunoglobulin A deficiency, and common variable immunodeficiency (Chapter 34).

Studies of leukemia in identical twins have shed light on the etiology of childhood ALL. Although ALL is not hereditary, there is markedly increased risk of leukemias in identical twins. If leukemia occurs in one identical twin, the other twin generally has a 10-20% chance of developing the disease by the age of 10 years. This phenomenon has promoted the hypothesis that at least two genetic hits are required for the development of ALL⁵ (Fig. 76.1). The first occurs during fetal lymphopoiesis and results in clonal proliferation of a preleukemic clone. Molecular studies have demonstrated that intrauterine metastasis of such a preleukemic clone from one twin to the other via their shared placental circulation is responsible for the concordant leukemia. These studies have also demonstrated that additional genetic hits in the preleukemic cells occur after birth and are required for the development of full-blown leukemia, which explains the less than 100% concordance. The initial findings in identical twins with leukemia have been extended to sporadic ALL; in at least 70% of patients the preleukemic clone can be detected molecularly in the neonatal blood samples collected after birth (known as Guthrie cards). More recently, molecular analysis of cord blood of normal infants has demonstrated that the occurrence of a preleukemic clone carrying a leukemia-defining chromosomal translocation is very common (up to one of every 20 newborns). Only 1% of children born with such a preleukemic clone will develop leukemia, making a molecular screen for early diagnosis of childhood ALL impractical.

Fig. 76.1 A model for the development of childhood acute lymphoblastic leukemia (ALL). The first acquired genomic hit (e.g., chromosomal translocation or change in chromosomal copy number) occurs during fetal hematopoiesis and results in clonal proliferation of a preleukemic clone. This event is common, occurring in up to 1 in every 20 children. Additional genetic aberrations occurring after birth are required for the development of ALL. These events are rare and are estimated to occur in about 1% of children born with a preleukemic clone.⁵

The causes of the relatively rare postnatal leukemogenic genetic hits are unknown. Although environmental agents such as ionizing radiation and chemical mutagens have been implicated in the induction of ALL, almost all cases lack discernible etiologic factors. As the risk of B-cell precursor ALL during early childhood is markedly increased by higher socioeconomic status and suburban style of living, in which the exposure of children to infectious pathogens is typically delayed beyond the neonatal period, Greaves hypothesized that many childhood cases are the consequence of an abnormally late immunologic response to common infections. One proposed mechanism is that growth-inhibitory factors, such as interferon or transforming growth factor- β (TGF- β), secreted during this immune response, provide a survival advantage to a preleukemic clone, setting the stage for additional leukemogenic mutations.⁵ Recently, increased expression of interferon inducible genes has been observed in many cases of hyperdiploid ALL, possibly providing the first direct biological evidence for the potential involvement of the immune system in the pathogenesis of childhood ALL.⁷

IMMUNOLOGIC AND MOLECULAR CLASSIFICATION OF ALL

Immunologic classification

The subtypes of ALL are usually identified by their immunophenotype, which often resembles the lymphoid developmental stage in which the leukemic cell was arrested^{8,9} (Table 76.1).

B-cell precursor leukemias. These are the most common childhood leukemias. Pro-B ALL is characterized by expression of CD19 and CD34 without CD10. This is the most common leukemia of infants that usually contains rearrangements of the MLL gene on chromosome 11q23 and is associated with poor outcome. Leukemic blast cells of early pre-B ALL resemble normal B-lymphoid cell precursors. They express CD19, CD22, and CD79a. CD10 and terminal deoxynucleotidyl

transferase (TdT) are detectable in 90% of cases, and CD34 in more than 75% of cases. This is the most common type of ALL, often called 'common ALL.' In pre-B ALL cases lymphoblasts accumulate cytoplasmic immunoglobulin heavy chains but have no detectable surface immunoglobulins. This subtype also expresses CD19, CD22, and CD79a. This type of leukemia often contains a translocation that fuses the E2A gene on chromosome 19 with the PBX1 gene on chromosome 1.¹⁰ Leukemic cells that express both cytoplasmic and surface immunoglobulin heavy chains have been designated transitional pre-B ALL. The surface μ -chains on these leukemic cells are linked to pseudo-light chains (Chapter 4) as well as to CD79a and CD79b.

Mature B-cell ALL is the leukemic form of Burkitt's lymphoma (Chapter 77). As treatment for mature B-cell ALL is dramatically different from that for B-cell precursor ALL, it must be specifically ruled out before initiating therapy. Mature B-cell ALL cells express surface immunoglobulin μ heavy chains plus either κ or λ light chains. In most cases cells have an L3 morphology and express CD19, CD22, and CD20. They frequently express CD10 and CD23 as well. CD34 is absent.

T-cell ALL. In affluent countries, T-ALL occurs in 10–15% of children with ALL. Its prevalence is higher in nonaffluent countries, probably as a reflection of a lower incidence of the common B-lineage early-childhood peak. T-ALL is also more common in adults. T-ALL has a less favorable prognosis than B-cell precursor ALL.

T-cell ALL cells express surface CD7 and cytoplasmic CD3 (cCD3). More than 90% of T lymphoblasts also express CD2, CD5, and TdT. Three stages of immunophenotypic differentiation can be determined: early (CD7⁺, cCD3⁺, surface CD3⁻, CD4⁻, and CD8⁻), intermediate (cCD3⁺, surface CD3⁻, CD4⁺, CD8⁺, and CD1⁺) and late (surface CD3⁺, CD1⁺, and either CD4⁺ or CD8⁺). However, up to one-quarter of T-lineage ALL cases do not conform to one of these maturation stages.¹¹

T-cell receptor (TCR) proteins are heterogeneously expressed in T-lineage ALL. In approximately two-thirds of cases membrane CD3 and TCR proteins are absent. However, in half of these cases TCR proteins (TCR- β , TCR- α , or both) are present in the cytoplasm. When membrane CD3 and TCR chains are expressed, the $\alpha\beta$ form of the TCR predominates. Only a minority of cases expresses TCR $\gamma\delta$ proteins.

The expression of myeloid-associated antigens, such as CD13, CD15, CD33, or CD65, in leukemic lymphoblasts can complicate leukemia classification in early studies. The diagnosis of B-lineage ALL should be made when leukemic cells express cytoplasmic immunoglobulin, CD79a, or CD19 plus CD22, regardless of myeloid-associated antigen expression. Likewise, the diagnosis of T-lineage ALL should be made when leukemic cells express CD7 plus either surface or cytoplasmic CD3. Myeloid-associated antigen expression in ALL has no independent prognostic significance. These ALLs should be distinguished from true biphenotypic leukemias that usually express cytoplasmic myeloperoxidase. Biphenotypic leukemias are associated with poorer outcome and are often treated with acute myeloid leukemia protocols.

Genetic and molecular classification

Virtually every leukemic cell has acquired alterations in more than one oncogene. These alterations are manifest as gross numerical or structural aberrations that can be used to define a specific clinical subtype of ALL. The common and/or clinically significant genetic aberrations that are

typically found in ALL are reviewed in references 2 and 12 and summarized in Table 76.2.^{2,12}

Numerical chromosomal aberrations. Deviation from the normal chromosomal modal number is called aneuploidy and is the most common chromosomal aberration in cancer. High Hyperdiploid ALL (Fig. 76.2)A, containing between 50 and 60 chromosomes, is the most common type of B-lineage ALL in children and is associated with about 90% cure rate. Typically there is excess of specific chromosomes, most commonly chromosomes 6, 10, 14, 17, 18, 21 and X. Hypodiploid ALL (Fig. 76.2)B, containing less than 45 chromosomes is much rarer and is associated with a very poor prognosis.

Chromosomal translocations can be divided into two general subtypes;^{13, 14} The first is the translocation of a proto-oncogene into the proximity of a strong regulatory region, resulting in its marked overexpression. Often these translocations are mediated by the V(D)J recombination machinery (Chapter 4) and can be therefore viewed as unfortunate developmental “accidents” caused by the physiologic lymphocyte specific genomic instability. Such instability is necessary for the creation of the diversity required for the recognition of novel foreign antigens. Examples of these translocations are the activation of *MYC* oncogene by the t(8;14) translocation in Burkitt’s lymphoma and, the activation of the *SCL* (*TAL1*) gene by the t(1;14) translocation near the *SLF* gene on chromosome 1p32 in T-ALL. Most of the chromosomal translocations observed in T-ALL are of the latter type. The second is the creation of novel fusion proteins consisting of parts of the genes that participate in the chromosomal translocation. The mechanisms of these translocations are unclear. Most of the translocations characteristic of B precursor ALL are of this type, for example the t(12;21) fusion of the *TEL* (*ETV6*) gene on chromosome 12 with the *AML1* (*RUNX1*) gene on chromosome 21.

Amplifications and deletions of small chromosomal regions represent a second set of common structural aberrations. For example, deletion of the *INK4A* locus located on the short arm of chromosome 9, which codes for the tumor suppressor genes *P16* and *P14*, is often observed in T-ALL. Amplification of the *AML1* locus on the long arm of chromosome 21,

found in about 2% of B cell precursor ALL, has been associated with an extremely poor prognosis.

Oncogenic activating mutations in ALL are reported with an increasing frequency. The Notch pathway, which is normally involved in T cell development, has been recently reported to be activated by acquired

mutations in more than 60% of T-ALL.¹⁵ This finding is of potential therapeutic significance since novel β -secretase inhibitors, originally developed for treatment of Alzheimer's disease, block the Notch pathway. Another example is mutational activation of the FLT3 growth pathway, which is often observed in hyperdiploid and t(4;11) leukemias.

Table 76.3 Example of hematopoietic genes involved in the pathogenesis of leukemia

Gene(s) names	Normal hematopoietic development	Leukemic involvement
SCL (TAL1)	Hemangioblast specification. Erythro- and megakaryopoiesis	T-ALL
LMO1/2	Similar to SCL	T-ALL
NOTCH	T lymphocytes	T-ALL
HOX11	Spleen	T-ALL
E2A	T and B lymphocytes	BCP-ALL
PAX5	B lymphocytes	BCP-ALL, B-NHL
SLP-65	B lymphocytes	BCP-ALL
TEL	Bone-Marrow Hematopoietic Stem Cells	BCP-ALL, rarely myeloid malignancies
RUNX1 (AML1, CBFA2)	Definite hematopoiesis. Megakaryopoiesis and T lymphocytes	BCP ALL, AML (M0-M1) Hereditary FPD/AML
CBFB	Same as RUNX1	AML (M4e)
C/EBP 1-3	Myeloid cells	AML (M1, M2)
PU.1	Myeloid and Lymphoid stem cells	AML
GATA1	Erythropoiesis, Megakaryopoiesis and Mast cells	AML (M7) associated with trisomy 21
FLT3	Hematopoiesis and lymphopoiesis	AML and ALL
MLL	Hematopoiesis stem cells	AML and ALL

AML, acute myeloid leukemia; BCP-ALL, B cell precursor acute lymphoblastic leukemia; B-NHL, B cell Non Hodgkin Lymphoma; FPD, familial platelet disorder; T-ALL, T-cell acute lymphoblastic leukemia.

Many of the genes modified by chromosomal translocations, amplification, deletions or point mutations play important roles in normal lymphoid or hematopoietic development (Table 76.3). The acquired aberrations of these genes may promote malignant transformation by overexpression or aberrant expression (wrong cell or wrong developmental stage). The activation of Notch in T-ALL is a prime example. Conversely, the acquired genetic aberration may block the normal developmental function of the involved gene(s). For example, the *TEL-AML1* (*ETV6-RUNX1*) translocation occurs in about 25% of childhood B-precursor ALLs; *AML1* is required for embryonic hematopoietic development and for differentiation of the lymphoid and the megakaryocytic compartments. It is involved in multiple translocations, resulting in fusion proteins that are thought to block its normal function dominantly. TEL is required for maintenance of the hematopoietic stem cells. The normal TEL allele is lost in the majority of TEL-AML1 leukemia, which implies that inhibition of the normal function of TEL further facilitates the development of this subtype of leukemia.

MAJOR CLINICALLY RELEVANT MOLECULAR SUBTYPES OF ALL (TABLE 76.2)

B-lineage ALL

Hyperdiploid and TEL-AML1 ALL comprise the majority of 'common ALL' leukemias typical of young children, but are rare in adults with ALL. Both are associated with an extremely good prognosis. In contrast, hypodiploidy (fewer than 45 chromosomes) and the internal amplification of chromosome 21q (iAMP 21q) are both associated with a poor prognosis.^{16,17} Another poor-prognosis aberration is the *BCR-ABL* fusion created by the t(9;22) 'Philadelphia chromosome.' Its frequency is low in children (3–5%) but high in adults (at least 30%). These differences may

explain the poorer outcome of ALL in adults compared with children. The *MLL* gene located on chromosome 11q23 is involved in fusion translocations, with more than 80 different partner genes. The most common translocation in ALL fuses the *MLL* with the *AF4* gene on chromosome 4. This t(4;11) translocation is characteristic of infant leukemia and is associated with poor prognosis. Interestingly, translocations involving the *MLL* gene are commonly seen in secondary leukemias (mostly AMLs) that occur in patients treated with topoisomerase inhibitors for a variety of cancers (e.g., etoposide or doxorubicin). This association raises the possibility that infant leukemias with *MLL* rearrangements are caused by intrauterine exposure to an environmental topoisomerase inhibitor. This has prompted large ongoing epidemiological studies.

The clinical significance of the *E2A-PBX1* fusion caused by the t(1;19) translocation, which occurs in fewer than 5% of childhood ALL, remains unclear. It was associated with a worse prognosis for patients on treatment protocols that were mainly based on antimetabolite chemotherapy. However, with newer protocols that incorporate anthracyclines, this prognostic significance has been lost. Indeed, this type of ALL may be associated with a better outcome. The change in the prognostic significance of this particular translocation with improved therapy exemplifies the general principle that the prognostic impact of a clinical or biological parameter is highly dependent on the specific treatment protocol.^{2,3} The *E2A* gene is rarely fused with the *HLF* gene in the t(17;19) translocation. This is an extremely rare translocation that is associated with a clinical presentation of diffuse intravascular coagulation and hypercalcemia and an extremely poor prognosis.

T-lineage ALL

Although multiple genetic and molecular subtypes of T-ALL have been recently described, their clinical significance is presently unclear.^{12,18} Most of the genetic aberrations in T-ALL result in the abnormal expression of

transcription factors. Aberrant overexpression of the bHLH transcription factor SCL (TAL1) is found in at least 60% of T-ALL in children and in about a third in adults. The mechanism of its overexpression is unknown in about half of these patients. The LMO1 or LMO2 proteins are often co-expressed with SCL. Together with SCL, these two proteins regulate very early T-cell development. Their aberrant continued expression is believed to cause the differentiation arrest characteristic of T-ALL. The importance of this gene in leukemogenesis has perhaps been best demonstrated by the development of T-ALL in several patients with severe combined immunodeficiency where there was retroviral insertion into the *LMO2* gene with gene therapy (Chapters 35 and 101). Another set of common abnormalities in childhood T-ALL is the activation of either *HOX11L2* (*TLX3*) or, less commonly, *HOX11* (*TLX1*) by chromosomal translocations with the TCR loci. Other chromosomal rearrangements in T-ALL involve the bHLH transcription factor *LYL1*, the *MLL-ENL* fusion, and amplification of the *ABL* oncogene. Activating mutations in Notch1 have been reported in over 60% of patients with all karyotypic subtypes of T-ALL. This finding suggests that activation of the Notch pathway may contribute to enhanced proliferation of T-cell precursors, thereby 'setting the stage' for the occurrence of other leukemogenic translocations. One recent study reported that children with T-ALL carrying *NOTCH* mutations had better survival when treated using Berlin-Frankfurt-Munster protocols.¹⁹ This association requires independent verification from other clinical studies.

CLINICAL FEATURES

The clinical signs and symptoms of leukemia reflect the replacement of bone marrow cells by leukemic blasts and the infiltration of extramedullary sites by the leukemic cells. Anemia, thrombocytopenia, and neutropenia that result from bone marrow involvement may manifest as pallor, fatigue, petechiae, bleeding, or fever. Bone pain and arthralgias, the development of a limp, the refusal of the young child to walk, and even frank arthritis are not uncommon. The musculoskeletal symptoms may be confused with osteomyelitis or juvenile idiopathic arthritis, which may delay the diagnosis. Uncommonly, central nervous system (CNS) involvement may present with signs and symptoms of increased intracranial pressure, such as headaches and papilledema, or by cranial nerve palsies, nuchal rigidity and, rarely, as hyperphagia and obesity caused by infiltration of the hypothalamus. Overt testicular leukemia at diagnosis is rare and manifests by painless testicular enlargement. Mediastinal involvement, common in T-ALL, may lead to dyspnea, superior vena cava syndrome, and even frank respiratory failure.

CLINICAL PEARLS

ACUTE LYMPHOBLASTIC LEUKEMIA (ALL) AND RHEUMATOID DISORDERS

- >> ALL can mimic juvenile idiopathic arthritis (JIA) and other musculoskeletal disorders
- >> Leukemic blasts may be absent from the peripheral blood, hence bone marrow examination should be considered in any child with JIA, especially prior to commencement of steroid therapy.

Clinical laboratory findings often reveal anemia and thrombocytopenia. However, leukocyte counts may vary. Only 20% of children present with leukocyte counts greater than 50 000/ μ l, whereas up to 40% demonstrate leukocyte counts less than 10 000/ μ l. Leukemic blasts may or may not be seen on peripheral smears. Therefore the diagnosis of leukemia may occasionally be missed in routine automated blood count. Elevated serum lactate dehydrogenase activity, hyperuricemia, or hyperphosphatemia are commonly observed in patients with a large leukemic cell burden.

The diagnosis of ALL is established by bone marrow examination. The normal bone marrow contains less than 5% blasts. A minimum of 25% lymphoblasts on differential examination of the bone marrow aspirate is necessary for the diagnosis of ALL. Most children with ALL have a hypercellular marrow with blasts constituting 60–100% of the nucleated cells.

Traditionally, CNS leukemia is defined by the presence of at least 5 leukocytes/ μ l of CSF and the detection of leukemic blast cells, or by the presence of cranial nerve palsy or by retinal involvement, as detected by ophthalmoscopy. While overt CNS leukemia is relatively rare, submicroscopic CNS involvement is present at diagnosis in at least half of the patients, even in the absence of any neurological symptoms. Therefore CNS-directed therapy is routinely included in ALL therapy (see below).

The differential diagnosis of ALL includes neoplastic and nonneoplastic diseases. Because children with ALL present with a variety of nonspecific symptoms, several pediatric nonmalignant conditions may be confused with leukemia. Since treatment with steroids can mask the presence of ALL, *serious consideration of the diagnosis of ALL must be given before starting treatment with steroids to any pediatric nonmalignant disorder.* Bone marrow examination is recommended in case of uncertainty.

Idiopathic thrombocytopenic purpura (ITP) is a common cause of bruising and petechiae in children. ITP is characterized by the absence of any other hematological abnormalities. Bone marrow should be examined if anemia or hepatosplenomegaly is present. Infectious mononucleosis can present with fever, malaise, adenopathy, splenomegaly, rash, and lymphocytosis. Lymphocytosis accompanied by thrombocytopenia and immunohemolytic anemia may further confuse the diagnosis. The atypical lymphocytes may morphologically resemble leukemic lymphoblasts, although an experienced hematologist can usually easily distinguish between the two conditions. Rarely, flow cytometry may be necessary to distinguish between activated atypical lymphocytes and immature leukemic lymphoblasts. Occasionally bone marrow examination is needed. Leukemoid reactions, observed in sepsis, acute hemolysis, and other disorders are usually easy to distinguish from ALL by morphological examination of peripheral blood smear. Since ALL occasionally presents with pancytopenia, aplastic anemia must also be considered.

Between 5% and 10% of children with ALL are first evaluated at pediatric rheumatology clinics. Fever, arthralgias, arthritis, or a limp accompanied by anemia, mild splenomegaly, and lymphadenopathy may frequently be confused with juvenile idiopathic arthritis (JIA) (Chapter 53) or osteomyelitis. Several of these patients receive antibiotics and anti-inflammatory agents for several weeks to months before the diagnosis of ALL. Bone marrow examination should be seriously considered in such patients.

As leukemic lymphoblasts are small round blue cells when stained with hematoxylin and eosin, they may be rarely be confused with metastatic small round-cell pediatric tumors, including neuroblastoma, rhabdomyosarcoma, and retinoblastoma.

SPECIAL DIAGNOSTIC TESTS

The classification and risk stratification for treatment protocols of ALL are based on detailed immunophenotyping and genotyping analysis.²⁰ Immunophenotyping by flow cytometry is required for confirmation of the diagnosis of ALL and for determination of the specific immunophenotype. Flow cytometry of propidium iodide-stained lymphoblasts can be used to determine the DNA index for the diagnosis of numerical chromosomal aberrations. A high DNA index (> 1.16) is typical for good-prognosis high hyperdiploid ALL, whereas a low DNA index reflects hypodiploidy, which is associated with a poor outcome. Cytogenetic analysis is required for the determination of the major genetic subtypes. In most centers karyotype by classical cytogenetics (Fig. 76.2) is performed. However, because of lack of metaphases, the yield of karyotypic analysis of ALL in multicenter protocols is often less than 70%. Furthermore, the observed karyotype may be derived from normal bone marrow cells and not from leukemia blasts. This drawback can be overcome by interphase fluorescent *in-situ* hybridization (FISH), a technique that does not require metaphases, or by direct examination of the genes or their products (Chapter 101). All clinically relevant structural and numerical chromosomal aberrations can be detected by the use of commercially available FISH probes (Fig. 76.3). Fusion translocations, such as *BCR-ABL*, *TEL-AML1*, and *MLL-AF4*, can be detected by reverse transcriptase polymerase chain reaction (RT-PCR).

The elucidation of the human genome and the invention of microarray technologies are anticipated to revolutionize the diagnostics of leukemias. Several pioneering studies from St. Jude Children's Research Hospital, Memphis, TN, USA, have demonstrated the diagnostic power of microarray-based gene expression analysis of childhood ALL.^{21,22} Currently several prospective studies are comparing microarray technology with more conventional methods for identification of clinically relevant genetic subtypes of leukemia. It is highly likely that within the next 5 years microarray technology will be incorporated into the clinical diagnostics of leukemia.

PRINCIPLES OF THERAPY³

Supportive therapy is given before the initiation of leukemia-specific therapy and this includes hydration, treatment, and preventive therapy of hyperuricemia, blood and platelet transfusion, and treatment of emergencies such as respiratory insufficiency associated with mediastinal leukemia.

It is highly recommended that children and adults with ALL be treated in specialized centers as part of a clinical prospective study. Such clinical trials are the basis for the dramatic improvement in the ALL patient outcome that has been achieved over the last several decades.

Treatment of ALL is initiated with an intensive remission induction regimen. This is usually followed by risk stratification into several treatment arms based on molecular studies and response to initial therapy. An intensification course may be followed by another phase of reinduction. All protocols include a prolonged maintenance phase, which consists of low-dose oral chemotherapy continued for 2–3 years after remission. Continuous chemotherapy for at least 2 years is unique to ALL. This approach differs significantly from chemotherapy regimens involving several very intensive courses for a relatively short time that are typically used for mature B-cell or acute myeloid leukemias. This empiric evolution of vastly different treatment protocols for B-cell precursor ALL versus mature B-cell leukemias likely reflects fundamental differences in the biology of the relevant leukemic stem cell.

Typical remission induction regimens include a glucocorticoid (prednisone, prednisolone, or dexamethasone), vincristine, and L-asparaginase. Several protocols also add anthracycline. The rate of complete remission now ranges between 97% and 99% for children versus 75% and 90% for adults. Intensification therapy incorporates either high doses of multiple agents not used during the induction phase or repeats the induction regimen. Regimens used for children include high-dose methotrexate with or without 6-mercaptopurine; high-dose L-asparaginase given for an extended period; an epipodophyllotoxin plus cytarabine; or a combination of dexamethasone, vincristine, L-asparaginase, doxorubicin, and thioguanine,

Fig. 76.3 Molecular cytogenetic techniques for the diagnosis of chromosomal translocations in acute lymphoblastic leukemia (ALL). Panels A and B display interphase fluorescent *in-situ* hybridization (FISH) with probes to the *AML1* (*RUNX1*) gene on chromosome 21 (red) and to the *TEL* (*ETV6*) gene on chromosome 12 (green). Panel A displays a normal cell, and panel B displays a leukemic cell that has undergone a fusion *TEL-AML1* translocation (arrow). Panel C displays the same translocation as depicted in B, but on metaphase chromosomes. It uses a molecular cytogenetic technique called *spectral karyotyping* (arrows). Classical cytogenetic analysis often misses this translocation. (Courtesy of Dr. L. Trakhtenbrot.)

with or without cyclophosphamide. Another integral component of many protocols is reinduction therapy. This treatment employs drugs similar to those used during the initial phase of induction therapy and has improved the outcomes of both children and adults with ALL. Maintenance therapy consists of a combination of methotrexate administered weekly and mercaptopurine administered daily. Some protocols add intermittent pulses of vincristine and dexamethasone.

CNS prophylactic therapy consisting of cranial irradiation plus intrathecal chemotherapy that is introduced after the induction of complete remission became one of the cornerstones of ALL therapy in the 1970s. More recently, because of concerns about neurotoxicity and the occurrence of brain tumors, the regimen of choice tends to include both intensive intrathecal and systemic chemotherapy.

Allogeneic stem-cell transplantation is reserved for patients who have relapsed or who suffer from refractory leukemia, as well as for patients with very-high-risk leukemia, such as BCR-ABL leukemia with slow response to therapy. With improvements in the prevention of transplant-related toxicities, suitable marrow donors now include matched unrelated donors and, in some situations, two- and three-antigen-mismatched family members, as well as classic human leukocyte antigen (HLA)-identical siblings or single-antigen-mismatched family members. Umbilical cord blood and peripheral blood stem cells have also been used successfully.

PROGNOSTIC FACTORS (TABLE 76.4)

Therapy for ALL is based on adjustment of the intensity of therapy to the risk assessment of the relapse hazard.^{3,23} The two major clinical parameters of prognostic significance are age at diagnosis and leukocyte count. Favorable prognostic factors include presentation of the disease when the child is between 1 and 9 years of age and a leukocyte count less than $50 \times 10^9/l$. For adults, the outcome of therapy worsens with increasing age and leukocyte count; patients older than 60 years and/or leukocyte count $> 100 \times 10^9/l$ have a particularly poor treatment response. Girls fare somewhat better than boys and in some protocols boys are treated for 3 instead of 2 years. Hyperdiploidy (> 50 chromosomes) and *TEL-AML1* are favorable prognostic factors that correlate strongly with age and white cell count.

MLL gene rearrangements lead to a less favorable prognosis, especially the *MLL-AF4* fusion. This fusion translocation is mostly detected in infant leukemia. The presence of the Philadelphia chromosome encoding the BCR-ABL fusion also confers a poor prognosis. Patients with either of these abnormalities are stratified into a high-risk treatment arm in all current protocols. Also associated with bad prognosis is hypodiploidy and amplification of the *AML1* region on chromosome 21. Traditionally patients with T-ALL tended to fare worse than those with B-lineage ALL. However, these differences appear to have been eliminated with the introduction of many modern protocols.

The most significant prognostic factor is the initial response to therapy. A rapid clearance of leukemic cells from the blood or bone marrow confers a favorable prognosis. A child with BCR-ABL positive ALL who presents with a low leukocyte count and in whom all blasts have disappeared from the peripheral blood after 1 week of steroid therapy is likely to do better than a similar child with hyperdiploid leukemia who has not significantly reduced the blast count after 2 weeks of therapy. The level of minimal residual disease (MRD) after the induction of clinical remission has also emerged as a powerful tool for gauging treatment response and predicting outcome.

WHERE IMMUNOLOGY MEETS ONCOLOGY
– MINIMAL RESIDUAL DISEASE

Modern treatment protocols lead to morphological complete remission, defined as less than 5% blasts in the bone marrow examination, in the majority of patients. If treatment is discontinued at that stage, most patients will eventually relapse. Indeed, all prospective clinical studies have shown that ALL should be treated for at least 2 years. These facts indicate that viable clonogenic malignant lymphoblasts continue to persist even after the completion of remission induction, even though the patient may be in clinical and morphological remission. Indeed, by this criterion patients may have as many as 10^{10} undetectable neoplastic cells when in remission. Since leukemic cells have to constitute at least 1–5% of the nucleated cells in the bone marrow in order to be detected by microscopic examination, morphological examination is clearly inadequate for evaluation of the quality of remission. Therefore more sensitive

Table 76.4 Major prognostic factors in acute lymphoblastic leukemia^a

Prognostic factor	Good prognosis	Worse prognosis
Age at diagnosis	1 < age < 10 (6) years	< 1 year; > 10 years (children) > 60 years (adult)
Peripheral blood WBC	< 50 000/ μ l	
Response to therapy	Early response to therapy; negative MRD at the end of induction	Slow response to therapy High MRD
Genetic abnormalities	Hyperdiploidy (> 50 chromosomes); TEL/AML1 (ETV6/RUNX1)	BCR/ABL MLL/AF4 Hypodiploidy < 45 chromosomes

MRD, minimal residual disease; WBC, white blood cells.

^aThe most important prognostic factor is the *treatment protocol*. Thus the prognostic significance of various clinical and laboratory variables may differ between protocols. Here, the significant parameters common to most studies are listed.

techniques for detection of rare leukemic cells are required. This is the rationale behind the recent incorporation of modern techniques of detection of MRD into treatment protocols of childhood ALL.

RT-PCR is an extremely sensitive technique for evaluation of residual leukemic cells that carry fusion translocations (such as *BCR-ABL* and *TEL-AML*). However, the majority of the leukemias lack these translocations. During the last decade, two general methodologies for sensitive detection of submicroscopic residual leukemic cells have been developed. These methodologies could not be developed without an understanding of the scientific basis of the developmental phenotype of immune cells (Chapters 8 and 9) and of the elaborate process of immunoglobulin gene rearrangements (Chapter 4).

The most widely studied DNA-based MRD methodology is based on the identification of clonospesific rearrangements of immunoglobulin genes or T-cell receptors (IgTCR-PCR).²⁴ This approach exploits the physiologic process of somatic rearrangement of Ig and TCR gene loci that occurs during early differentiation of any lymphocyte. Thus, any single lymphocyte carries a unique rearrangement that is not shared by any other lymphoid cell. This process ensures the level of diversity of the immune response against an unlimited number of antigens. Since leukemia is clonal, that is, it originates from one lymphoid cell, all the leukemic cells of a particular person carry the same Ig and/or TCR rearrangements. Because leukemic cells are genetically unstable, they often

(> 90% of the cases) carry multiple rearrangements, a fact that facilitates the usefulness of using these rearrangements as a clonal marker for MRD detection. The major advantages of this technique are the exquisite sensitivity (at least 10^{-5}), reliability, reproducibility, and its applicability to more than 90% of children with ALL. Its biggest disadvantages are the costs and complexity.

Current strategies for flow cytometric detection of MRD rely on combinations of leukocyte markers that do not normally occur in cells of the peripheral blood and bone marrow. Such leukemia-associated phenotypes can be identified by two-, three-, or four-color staining techniques (Fig. 76.4).²⁵ Flow cytometric analysis allows the detection of one leukemic cell among 10^4 or more normal cells. The advantages of flow cytometry for MRD detection are adequate sensitivity and the presence of immunophenotyping facilities in most major centers that facilitates the timely performance of the analysis on fresh cells at a reasonable cost. There are a few disadvantages, however. It requires a flow cytometry operator with a high level of expertise and it is more difficult to standardize compared to PCR. Moreover, it may be difficult to distinguish between regenerating B-cell progenitors and leukemic blasts. Thus flow MRD is most reliable and sensitive at very early stages (up to 4 weeks) of therapy.

Many clinical studies on a relatively small number of patients (which include a total of several hundred patients) enrolled on ALL treatment protocols revealed strikingly similar results. Fast clearance of leukemic

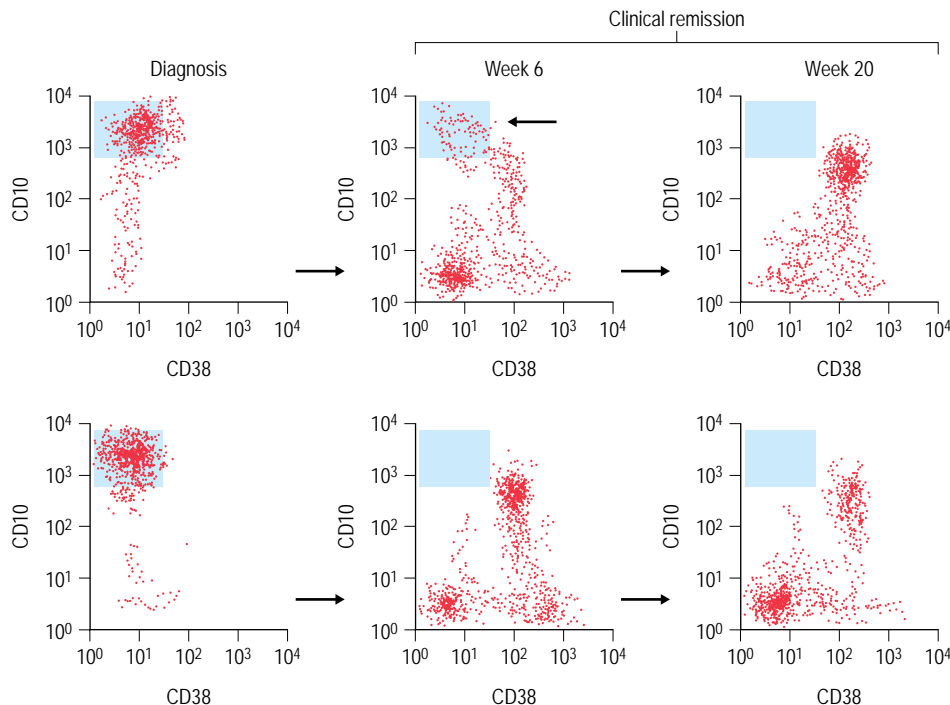

Fig. 76.4 Different kinetics of leukemia cyto-reduction revealed by minimal residual disease (MRD) studies with flow cytometry.⁵¹ The left panels illustrate the leukemia-specific immunophenotype (CD10⁺, CD38⁻) determined at diagnosis in two children with ALL. This phenotype is not found in normal bone marrow. Bone marrow samples were collected during clinical remission from both patients. In one patient (top panels), 0.04% of mononuclear cells expressed the leukemia-specific phenotype at week 6. MRD was undetectable by week 20. In the other patient (bottom panels), a profound remission (MRD < 0.01%) was achieved by week 6 and maintained at week 20.

blasts to below 10^{-4} cells within the first 2–4 weeks of therapy is detected in about 40% of children with ALL and is associated with an extremely good prognosis. Conversely, the presence of more than 0.1% blasts after 2 or 3 months of therapy defines a very high-risk group.^{9, 26–29} These initial findings have led the BFM-AEIOP study group to initiate a prospective study on children with ALL that utilize the MRD level determined by IgTCR-PCR for risk classification. Initial, as-yet unpublished analysis of more than 2500 patients (presented in the iBFM Study Group meeting 2006), confirms the strength of PCR MRD over genetic classification as a prognostic marker.

At present MRD studies have been incorporated into most treatment protocols. Patients with high MRD are stratified into a high-risk arm and receive more intensive chemotherapy. A few protocols are also testing whether therapy can be reduced for patients with no detectable MRD after 2–4 weeks of therapy, irrespective of their clinical presentation. While the robustness of MRD as the most sensitive and reliable prognostic indicator in ALL has been confirmed, at present it is unclear if adjustment of therapy to the MRD level will improve survival for these higher-risk patients.

COURSE AND PROGNOSIS

With current protocols, the cure rate of children with ALL is about 80%.^{3, 4} More than 90% of children with low-risk leukemia and about 70% of children with high-risk leukemia are cured. The cure rates of adult is significantly lower – around 35–40%^{30, 31} – probably because these adults tend to suffer with ALL genetic subtypes that have an inherently unfavorable prognosis.

Most relapses occur during treatment or within the first 2 years after completion of therapy. However, late relapses (even 10 years after diagnosis) are increasingly seen, especially in ALL containing the *TEL-AML1* genotype. In about 5% of cases, the clinical relapse occurs in an extramedullary site, most often the CNS or, in males, the testes. Leukemic relapse occasionally occurs at other sites, including the eye, ear, ovary, uterus, bone, muscle, tonsil, kidney, mediastinum, pleura, and paranasal sinuses. The prognosis of relapse depends on the time from diagnosis (earlier is worse), leukocyte count, immunophenotype, and genotype (similar to the prognostic factors at diagnosis). Isolated extramedullary relapse carries a better prognosis. Although some relapses can be treated by chemotherapy alone, most are being treated by stem-cell transplantation. At present, the most important prognostic factor is the MRD level before transplant. More than half of the late relapses (more than half a year since completion of therapy) in patients with “good-prognosis” ALL are curable. The prognosis of early relapsers is grim.

TREATMENT SEQUELAE

Improvements in supportive care reduced the rate of early death to less than 2% in the 1990s. However, the death rate among elderly patients during remission induction therapy remained as high as 30% due to hematological, hepatic, and cardiac toxicities.

Long-term toxicity is also of major concern for children cured from ALL. Aseptic necrosis of various bones has emerged as a common late toxicity of glucocorticoids, especially in adolescent girls treated with dexamethasone.^{32, 33} The rate of long-term neurotoxicity has been reduced due to replacement of cranial irradiation with high-dose and intrathecal methotrexate. However, it remains unclear whether intensive methotrexate therapy may lead to very

late neurodegeneration effects. The dose of anthracyclines used in most ALL protocols is unlikely to produce severe cardiomyopathy. However, secondary cancers are a major concern. The development of therapy-related acute myeloid leukemia has been linked to the use of topoisomerase II inhibitors (teniposide and etoposide), and the risk is apparently dependent on the treatment schedule and the concomitant use of other agents (e.g., L-asparaginase, alkylating agents, and perhaps antimetabolites). Children who received cranial irradiation at 6 years of age or younger are most susceptible to the development of brain tumors. This risk is increased by the intensive use of antimetabolite drugs before and during cranial irradiation.³⁴

Recent long-term follow-up studies reported from Scandinavia of children cured of ALL confirm excellent long-term outcome, judged by their socioeducational achievements and by reproductive success resulting in healthy children.³⁵

CURRENT CONTROVERSIES AND FUTURE PERSPECTIVE

The high cure rates in patients with ALL (nearly 80% of children and 40% of adults) attest to the steady progress that has been made in treating this disease. A further increase in cure rates will require efforts to maximize the efficacy and minimize the toxicity of current therapy. A major challenge is to improve risk classification to optimize therapy for individual patients. Progress in pharmacogenomics may allow personal tailoring of dosage of specific drugs. The role of microarray gene expression analysis is still unclear, as well as the best technical approach to MRD. Currently MRD measurement can reliably identify the extremely good and poor-risk patients. However, about half of the patients belong to an “intermediate-risk” group in which most of the relapses occur. Optimization of diagnosis and treatment of this group of patients are among the current major challenges.

The development of new treatments for ALL is a major challenge, especially for the high-risk group of patients. Given the rarity of ALL, compared with epithelial cancers, the development of specific new drugs is unlikely. Imatinib, the prototype of targeted therapy against BCR-ABL chronic myeloid leukemia, has only modest activity against BCR-ABL ALL. New ABL and dual kinase inhibitors may prove more promising. Genetic modifications of allogeneic and autologous cells may be another future approach for targeted therapy of ALL. The reliable identification of extremely high-risk ALL patients by MRD measurement permits the examination of new therapies early in the course of therapy, as a phase I/II window. Such studies within the context of large cooperative trials may further improve the survival of patients with high-risk ALL.

CHRONIC LYMPHOCYTIC LEUKEMIA

CLL is a lymphoproliferative indolent neoplasm of mature peripheral circulating B cells. It is the most common leukemia in adults of the western hemisphere (Fig. 76.5). According to the World Health Organization classification, CLL and small lymphocytic lymphoma (SLL) are considered to be one disease at different stages.³⁶ CLL originates from a clonal lymphoid-evolved mature stem cell which can be identified by its distinct B-cell immunoglobulin gene rearrangement. Both clinically and at the molecular level, CLL is a heterogeneous disease. Some patients have an indolent course with distinct

Fig. 76.5 A Giemsa-stained peripheral blood smear displaying chronic lymphocytic leukemia cells.

genetic markers, whereas others suffer with a more rapid and aggressive disease characterized by a separate molecular signature. During its progression, CLL may be associated with significant immune deficiencies and autoimmune phenomena that can complicate its course and treatment. These abnormalities may be so profound that they alter the nature of the disease. They are attributed to the clonal nature of its B-cell origin. More than 95% of patients have a B-CLL phenotype; the remainder express T-CLL.

EPIDEMIOLOGY

The clinical diagnosis of CLL requires absolute lymphocytosis of more than 5000/ μ l mature lymphocytes in the peripheral blood. The extensive use of automated peripheral blood lymphocyte counts has led to an increase in the rate of diagnosis of asymptomatic patients with CLL. The incidence rate of CLL increases logarithmically from age 35, with a median age at the time of diagnosis of 65 years. There is a male predominance, and the disease exhibits geographic and ethnic variation. In the USA, CLL is reported to occur with equal incidence among residents of sub-Saharan African and European descent, but it is uncommon among those of East Asian descent. The reported incidence is 4.3/100 000 per year. Because many of these patients may never require tissue diagnosis or inpatient treatment, they are not likely to be recorded by a tumor registry. Thus the true annual incidence of the disease is likely to be higher than previously appreciated (6.8/100 000 population).³⁷ It is important to note that, when techniques of higher sensitivity are used, monoclonal populations of B lymphocytes that are indistinguishable from CLL cells can be found in the blood of 3.5% of persons older than 40 years of age.³⁸

The etiology of CLL is largely unknown; however, as with other forms of malignancy, there is increasing evidence for the role of inherited factors in its development. Family surveys show a genetic predisposition in first-degree relatives. Anticipation, the phenomenon of earlier onset and more severe phenotype in successive generations, has been reported in CLL families.³⁹

PATHOGENESIS AND THE BIOLOGY OF LEUKEMIC LYMPHOCYTES

CLL was initially considered to be a single homogeneous disease of accumulating immature, immune-competent, minimally self-renewing B cells. It is now viewed as two related entities, both of which originate from B lymphocytes while differing in their state of activation and maturation.⁴⁰

Normal B-lineage cells mature in the bone marrow, where they undergo rearrangement of immunoglobulin variable (V), diversity (D), and joining (J) gene segments to create the rearranged variable domains that encode the antigen-binding portion of their antigen receptor, immunoglobulin (Chapters 4 and 8). When an antigen of adequate affinity engages their B-cell receptor, the cell enters a germinal center located in a lymphoid follicle, where, as a centroblast with appropriate T-cell help, it rapidly divides and its V genes undergo somatic hypermutation. This process introduces mutations in the rearranged gene segments that code for the binding site of the receptor. Through these mutations, the receptors of the descendant B cells, called centrocytes, acquire new properties. Cells with receptors that have enhanced antigen-binding affinity proliferate in the presence of the antigen, whereas centrocytes with receptors that no longer bind the antigen (or bind autoantigens) are normally eliminated. Once the centrocytes are selected, they become plasma or memory B cells (Fig. 76.6). Thus, the CLL cell population may originate from a clone with few or no V-domain mutations, or from a more mature clone whose V domains have undergone the hypermutation process. This creates two separate pools of B cells, both of which originate from antigen-stimulated mature B lymphocytes. In CLL with mutated Ig genes, the proliferating B cell is likely to have traversed a germinal center, whereas in CLL with unmutated Ig genes the malignant B cell is more likely to derive from a pregerminal center naïve B cell.

Mutations of V genes are detected by comparing DNA sequences of the genes in B cells with corresponding genes in the germline. A sequence that differs from its germline counterpart by 2% or more is defined as mutated. This mutational status strongly correlates with prognosis, in that patients with an unmutated clone have a much worse prognosis than patients with mutated clones.⁴¹ These patients may differ also in their association with specific genetic aberrations. 11q22-23 (the ataxia-telangiectasia mutated gene) or 17p13 (the p53 gene) deletions are associated with a poorer outcome and with an unmutated VH profile. These genes regulate apoptosis and resistance to chemotherapy. 13q14 deletion or a normal karyotype are associated with a mutated profile of V genes, and are considered to carry better prognosis. There is controversy as to whether trisomy 12 is associated with an unmutated status.⁴² These chromosomal aberrations appear to have separate and independent (unrelated to the mutational status) effects on the patient's prognosis.⁴³

Antigens typically found on the surface of the membrane of B-CLL cells include CD19, CD21, and CD23, with reduced levels of membrane IgM, IgD, and CD79b. This is a phenotype most consistent with that observed among mature activated B cells. The pathological features of biopsied lymph node are those of an SLL.⁴⁰ The coexpression of CD5, a T-cell-associated antigen, is a phenotypic characteristic and part of the disease-defining criteria. CD5⁺ B cells can be found in the peripheral blood of normal adults, suggesting that specific subsets of CD5⁺ B cells from the mantle zone may be the normal counterparts of B-CLL.^{40, 44} The low expression of the BCR is the hallmark of CLL cells, and appears to contribute impaired responses to BCR stimulation. Studies analyzing

Fig. 76.6 Chronic lymphocytic leukemia (CLL) and B-cell development. The phenotype displayed by a B-cell lymphoproliferative disorder reflects the stage of normal B-cell development it achieved prior to its final transformation. Development begins in the fetal liver and in fetal and adult bone marrow. Maturing B cells exit to the peripheral blood, but typically require entry into the germinal center (GC) in order to undergo somatic hypermutation. The CLL cells that express unmutated immunoglobulin variable domains thus likely underwent final transformation prior to entry into the GC, whereas those that express mutated variable domains likely transited the GC and then underwent final transformation. Transformation in pro- and pre-B cells typically gives rise to acute lymphoblastic leukemia. Transformation of intermediate stages can give rise to mantle-zone lymphomas. Transformation at later stages can give rise to marginal-zone lymphomas and plasma cell-derived multiple myeloma.

signal competence have shown that unmutated CLLs tended to express higher amounts of the BCR and to respond better to stimulation when compared with mutated CLLs. These results suggest that unmutated CLLs may be more likely to preserve their ability to respond to BCR stimulation, whereas mutated ones most closely resemble the phenotype observed in anergic B cells.⁴³

The CD38 surface molecule supports B-cell interactions and differentiation, and under certain circumstances augments signaling of BCR, delivering signals that regulate the apoptosis of B cells.⁴³ It also correlates with the mutational status of the BCR and confers bad prognosis. Another molecule that influences the BCR is zeta-associated protein 70 (ZAP-70). High levels of this receptor-associated protein tyrosine kinase (usually found in T and natural killer (NK) cells, but not in normal B cells) are detected in the majority of unmutated CLLs. These levels may be measured by routine flow cytometry studies and correlate not only with the an unmutated V domain state, but also independently with prognosis.⁴⁵

The role of the antigenic stimulus for promotion of proliferation has also been studied. The BCRs from various patients are similar, suggesting a common pathogenetic antigen. The source of this putative common antigen – bacteria, virus, or rather an environmental factor – has yet to be

identified.⁴⁰ The possibility that an autoantigen provokes clonal expansion is supported by the finding of some mutated immunoglobulin V genes that encode poly-reactive receptors.

The microenvironment may also play a role in the pathogenesis of CLL.^{40, 46} Interactions with stromal cells rescue CLL cells from apoptosis *in vitro*, activated T cells support the growth of CLL cells, and cytokines such as interleukin-4 (IL-4) and vascular endothelial growth factor and chemokines such as SDF-1 support the expansion of CLL clones.

CLL is classically characterized by the accumulation of mature B cells that evade apoptosis, with high levels of the BCL2 anti-apoptotic protein.⁴⁶ Contradicting this dogma is the measurement of CLL kinetics, which has shown CLL cells to proliferate at a high dynamic rate of up to 1% of the clone per day.⁴⁷ This finding suggests that CLL may not only be an accumulative disease, but also has a proliferative element.

CLINICAL FEATURES OF CLL

The clinical diagnosis of CLL requires an absolute lymphocytosis of greater than $5000 \times 10^9/l$ mature-appearing lymphocytes in the blood smear and that persists for a period of at least 4 weeks. By immunophenotype, the

CLINICAL PEARLS

CLINICAL MANIFESTATIONS OF CHRONIC LYMPHOCYTIC LEUKEMIA

- >> Absolute blood lymphocytosis $>5000/\text{mm}^3$ sustained over a period of 4 weeks (to exclude transient lymphocytosis-related conditions as viral infections)
- >> At least 30% lymphocytes in a normo- or hypercellular marrow
- >> Lymphocytes are phenotypically monoclonal, i.e., express both B-cell markers (CD19, CD23, CD20) and the pan-T-cell marker (CD5)
- >> Lymphocytes are morphologically mature-appearing
- >> Most patients will have some degree of lymphadenopathy on physical examination
- >> Progression and the need for treatment are according to lymphocyte doubling time, bulky symptomatic disease, anemia, thrombocytopenia, and autoimmune phenomena

cells predominantly display the mature B-cell markers (CD19, CD20, and CD23) as well as the pan-T-cell CD5 antigen in the absence of all other T-cell markers. As many as one-quarter of patients are asymptomatic at the time of diagnosis.^{48,49} For those who are symptomatic, clinical characteristics at presentation include lymphadenopathy (87%), splenomegaly (54%), hepatomegaly (14%), leukocytosis, anemia, and thrombocytopenia (20%). Very high blood cell counts are rare at the time of initial diagnosis, but may develop over time. Hyperleukocytosis causing leukostasis and needing emergency treatment is extremely rare, but has been reported in isolated cases.⁵⁰ In addition to the lymphoid tissues, solid organs and the skin may occasionally be affected. A full diagnostic evaluation typically requires a bone marrow aspirate and biopsy. An interstitial or nodular infiltration pattern correlates with a better prognosis than the diffuse type.^{49,51}

A prognostic evaluation, especially in young patients or early stages of CLL, should include evaluation of the CD38 and ZAP-70 immune phenotype, cytogenetic analysis for chromosomal abnormalities, and an assessment of the extent of somatic hypermutation in the CLL immunoglobulin H-chain variable domain. Lymph node biopsy is not necessary, but if performed may lead to the diagnosis of SLL, which is currently considered a separate manifestation of the same disease. A wide spectrum of immune deficiency and autoimmune phenomena is characteristic of CLL, and is discussed in greater detail in the following section on immunologic aspects of the disease. The differential diagnosis includes other low-grade lymphoproliferative disorders such as the leukemic phase of lymphoma and mantle-cell lymphoma (usually negative for CD23), hairy-cell leukemia (CD5 and 21-negative and CD103 and 25-positive), T-cell leukemia (expressing the CD3, CD4, and CD7 T-cell markers) and prolymphocytic leukemia (PLL), which is distinguished by morphologically immature-appearing cells and the presence of FMC7 and CD79b on the cell surface. T-cell CLL is rare ($< 5\%$).

The oldest system of CLL risk stratification relies on measurement of disease bulk. Rai et al.⁵² reported a staging classification ranging from stage 0 to 4 that uses lymphadenopathy, splenomegaly, anemia, and thrombocytopenia as markers of progressive disease bulk. Subsequently,

Binet et al.⁵³ reported a staging system ranging from stages A to C that relies on the number of enlarged lymph node regions and the presence of anemia or thrombocytopenia (Table 76.5).⁵¹ Both staging systems place patients into one of three prognostic groups: good, intermediate, and poor prognosis. Placement into the last group makes the patient a candidate for treatment. These staging systems have been very useful for defining whom to treat at the time of diagnosis, but not at predicting who will subsequently need treatment.³⁸

One-third of patients never require treatment and have a long survival. In another third, an initial indolent phase is followed by disease progression. The remaining third tends to exhibit aggressive disease at the onset and needs immediate treatment. However, even in the low-risk group (stage A Binet or stage 0 Rai), over 25% of these indolent cases die of causes related to CLL, 40% progress to advanced stages, and 50% ultimately require treatment. These results demonstrate that neither the Rai nor the Binet staging system is able to predict accurately which patients among the good-prognosis group will eventually develop progressive disease.

The most powerful predictors for rapid and aggressive progression are the mutational status and chromosomal abnormalities, as described above (Fig. 76.7 and Table 76.5).⁴⁰ The mutational profile has the advantage of remaining constant during disease evolution, in contrast to genomic aberrations and surface markers such as CD38. Since the ability to sequence immunoglobulin genes is not available in most laboratories, a surrogate assay such as the ZAP-70 molecule, as identified by flow cytometry, may become the laboratory test of choice. This test is still not widely used due to the technically difficult nature of the flow cytometric assay.⁵¹ Another marker, β_2 -microglobulin, was reported in retrospective series to correlate with disease burden and prognosis. However, this was not reproduced in a prospective study.^{48,51}

Clonal evolution with the transformation to a more aggressive lymphoid malignancy, termed Richter's transformation, includes other lymphoid malignancies that develop in patients with CLL. Classically defined as high-grade large B-cell lymphoma, its definition has been extended to include PLL, Hodgkin disease (the so-called Hodgkin variant of Richter's transformation), lymphoblastic lymphoma, and hairy-cell leukemia. In rare cases, patients with B-cell CLL may develop high-grade, T-cell non-Hodgkin lymphoma (NHL).⁵³ These transformations are relatively uncommon (2–14%) and are characterized by progressive lymphadenopathy and constitutional symptoms. The prognosis is generally ominous.

TREATMENT

As CLL remains an incurable tumor, treatment may be delayed and the patient monitored until becoming symptomatic.^{48,49,51,55} Guidelines include the development of symptoms, worsening anemia and/or thrombocytopenia, autoimmune cytopenias, progressive splenomegaly, progressive lymphadenopathy, or lymphocyte doubling time of 6 months. No prospective data exist yet to support the early treatment of patients with adverse prognostic features. On the other hand, many patients will be treated with supportive care only because of advanced age and comorbidities.

Chlorambucil, alone or combined with corticosteroids, is the most commonly used drug. It is advantageous in relieving symptoms, even in advanced disease. However, several randomized trials have failed to demonstrate improved survival, and hardly any patient achieves complete

Table 76.5 Major factors associated with prognosis^{38, 40–43, 45, 51–52}

	Definition	Median survival (years)	Used in clinical practice
Rai stage			
0	Leukocytosis	12.5	Yes
1	Leukocytosis and lymphadenopathy	8.4	
2	Lymphocytosis plus hepatosplenomegaly	6.9	
3	Lymphocytosis plus anemia (< 11 g/dl)	1.5	
4	Lymphocytosis plus thrombocytopenia (< 100 000 × 10 ⁹ /l)	1.5	
Binet stage			
A	Leukocytosis and lymphadenopathy	Age-matched	Yes
B	Lymphadenopathy of more than two involved areas	7	
C	Anemia or thrombocytopenia	2	Yes
β ₂ -microglobulin	Normal	9.7	
	Elevated	4.5	
CD38			Yes
Early-stage CLL	> 30%	2.9–<10 years	
	< 30%	9→ 26 years	
Chromosomal aberrations (FISH analysis)	17p-	2.7	Sometimes
	11q-	6.5	
	Trisomy 12	9.5	
	Normal karyotype	9.3	
	13q-	11.1	
ZAP70			Not available
Early-stage CLL	> 20%	7.5	
	< 20%	Not reached	
Mutational status	Unmutated	5.7–< 9.9 years	If available
	Mutated	10.2→ 24 years

CLL, chronic lymphocytic leukemia; FISH, fluorescent in-situ hybridization; ZAP70, zeta-associated protein 70.

remission. Purine analogues with or without cyclophosphamide were demonstrated to induce higher response rates when compared to chlorambucil, with some patients achieving complete remission.

The CD52 antigen is present on lymphocytes (B, T, and NK cells), monocytes, and some granulocytes. The humanized monoclonal anti-CD52 antibody (CAMPATH-1, alemtuzumab) has been shown to have an effect against B-CLL cells. Studies demonstrated high activity of this drug in previously treated and even refractory CLL patients, as well as in eliminating MRD, especially in the bone marrow.⁵⁶ Nevertheless, the resulting depletion of B cells and T cells places patients at higher risk for severe infectious complications, particularly CMV reactivation.⁴⁵ Anti-CD20 (rituximab, MabThera) as single agent shows limited efficacy in CLL, possibly because of the weak receptor expression on CLL cells. However, in combination with chemotherapy and particularly fludarabine it appears to act synergistically and to achieve high rates of response, including molecular complete remission.^{48, 49} The combination of alemtuzumab with rituximab had a good but limited overall response.⁵⁶ Other immune-based therapies include lumiliximab (anti-CD23), apolizumab

(anti-HLA-DR), and anti-CD40. These are being tested with or without the addition of chemotherapy.

Some immunologic novel futuristic approaches involving expanded autoreactive activated T cells have shown a safe profile and modest clinical improvements in phase I trials, as have vaccination strategies utilizing autologous leukemic cells transduced with different proapoptotic receptors (i.e., CD40 and CD95).⁵⁶

Allogeneic hematopoietic stem cell transplantation (HSCT) is the only curative CLL treatment. Allogeneic HSCT relies on myeloablative doses of chemoradiotherapy, making this treatment unacceptably risky for the majority of CLL patients. In nonmyeloablative or reduced-intensity approaches, rates of engraftment are similar to fully ablative conditioning regimens with lower rates of early toxicity. Early evidence suggests that the graft-versus-leukemia effect is present against the disease. Studies involving autologous transplantation and high-dose chemotherapy for CLL have a limited survival advantage. Relapses are frequent and there is a high incidence of secondary myelodysplastic syndrome and acute myeloid leukemia.

Fig. 76.7 Risk markers and stratification in chronic lymphocytic leukemia (CLL). B-cell CLL can be divided into two different entities. Both express the B-cell surface antigens CD19, CD23, and CD20, the last at low levels. They also express the pan-T-cell antigen CD5. The unmutated form yields a worse prognosis, and features CD38 on its cell surface, intracellular zeta-associated protein 70 (ZAP-70), chromosomal aberrations as 17p- and 11q-, and high levels of soluble β_2 -microglobulin (β_2m). In contrast, the mutated form has a better prognosis, tends to lack CD38 and ZAP-70, and has a normal karyotype or is 13q-.

The present treatment criteria do not identify patients in early stages with adverse prognostic high-risk features. Nevertheless, the overall survival of CLL patients has globally improved from 5 to 8 years for Binet stage B patients and from 2 to 5 years for stage C patients. This consistent improvement could be due to subsequent treatment advances provided to patients failing to respond initial treatment.⁴⁹ Thus, pending ongoing clinical trials, it may become feasible to treat patients with good performance and early-stage status who also demonstrate unfavorable prognostic features.³⁰

IMMUNOLOGIC ASPECTS OF CLL

CLL is characterized by multiple immune deficiencies and autoimmune phenomena. It is reasonable to hypothesize that immune incompetence and autoimmunity are two sides of the same coin.⁵⁷

The pathophysiologic rationale

CLL cells secrete TGF- β , which is a potent inhibitor of B-cell proliferation, and release high levels of circulating IL-2 receptor, which downregulates T-helper function. B-CLL cells also fail to present soluble antigen and alloantigens, as do anergic normal B cells. Conversely, normal activated B cells are very effective antigen-presenting cells.⁵⁷

There is increasing evidence of T-cell dysfunction in CLL, which may contribute to the etiology and progress of the disease. An absolute CD8 lymphocytosis correlates with disease progression. Also, as found in autoimmune diseases, low expression of CD4 and CD8 is seen with abnormal expression of other surface molecules. In addition, the T cells in CLL patients were found to have profound abnormalities of their antigen receptor (TCR) repertoire⁵⁷ and appear dysfunctional in terms of cytokine secretion. Aberrant levels of interferon- γ , IL-2, IL-4, and

THERAPEUTIC PRINCIPLES

GOAL: TO AMELIORATE SYMPTOMS

- >> Chronic lymphocytic leukemia is incurable but the likelihood of complete remission is good and survival appears to be improving for high-risk patients
- >> Intervention in asymptomatic early stages should be limited to watchful waiting
- >> Supportive care (gammaglobulin replacement, blood supplements and erythropoietin, treatment of infections) should be provided as needed
- >> Conventional therapy includes steroids and/or chemotherapy (alkylating agents such as chlorambucil and cyclophosphamide, purine analogues such as fludarabine and cladribine, other lymphoma regimens)
- >> Chlorambucil is the most commonly used drug and works well to relieve symptoms
- >> Steroids can be very helpful for treating autoimmune phenomenon
- >> More recent approaches use targeted monoclonal antibody therapy with or without chemotherapy (i.e., rituximab and alemtuzumab)
- >> Autologous and allogeneic stem-cell transplantation are the only curative treatments, but require myeloablative chemoradiotherapy

CLINICAL PEARLS

IMMUNOLOGIC MANIFESTATIONS OF CHRONIC LYMPHOCYTIC LEUKEMIA

- >> Pan-hypogammaglobulinemia
- >> A monoclonal immunoglobulin peak, usually of the immunoglobulin M type
- >> Downregulation of T-cell function and aberrant cytokine production
- >> Defects in the complement system
- >> High risk of recurrent infections – encapsulated bacteria and opportunistic infections
 - >> Autoimmune-associated phenomena:
 - >> Autoimmune hemolytic anemia
 - >> Autoimmune thrombocytopenia
 - >> Pure red-cell aplasia and autoimmune neutropenia
 - >> Other autoimmune disorders (myositis, vasculitis, pemphigus vulgaris, acquired angioedema, and glomerulonephritis)

IL-6 production have been described⁵⁸ and are dependent on the number of leukemic B cells and disease stage. It is possible that progression of the disease leads to a decline in T-cell function, greater negative feedback by B cells on the T cells, enhanced cytokine production by the B cells, or a combination of these factors. An imbalance of cytokine production could contribute to the upregulation of BCL-2 anti-apoptotic activity.⁵⁹ T-cell dysfunction could also explain the higher incidence of autoimmune complications, such as autoimmune hemolytic anemia (AIHA), among patients treated with purine analogues, which induce T-cell depletion. Assuming that certain T-cell subsets prevent the development of autoreactive B cells, purine analogue-induced depletion of T-cell numbers may permit autoreactive B-cell clones to emerge and expand.⁵⁷ However, this last complication is mainly observed among heavily pretreated patients who have received purine analogues as salvage therapy.⁴⁹

Immunologic deficiencies

Patients with CLL are extremely sensitive to various infectious agents. A monoclonal immunoglobulin peak, usually of the IgM type, is found in 5% of CLL, and a small amount of a monoclonal component can be identified in the serum or urine of 60% of patients. Hypogammaglobulinemia occurs in at least 60% of B-CLL cases, and may include all three classes (IgG, IgA, IgM). The pathogenesis of hypogammaglobulinemia in B-CLL is poorly understood, as this phenomenon is rare in other B-cell malignancies except for multiple myeloma. Regulatory abnormalities in T cells may play a role in the induction of hypogammaglobulinemia, but may also result as a consequence of dysfunction of nonclonal normal B cells.⁴⁹ Low Ig levels correlate with recurrent infections of encapsulated organisms. Patients who receive intravenous immunoglobulin (Chapter 85) experience a decrease in the incidence of major bacterial infections.⁶⁰ Although it is costly, patients who have demonstrated a pattern of repeated serious infections should be treated with prophylactic IgIV.

Infections are a major cause of morbidity and mortality in CLL patients. Impaired humoral and cellular immunity, defects in the complement systems, and variable neutropenia, depending on marrow infiltrates, all contribute to the high rate of infections.⁶¹ It is estimated that up to 50% of patients have recurrent infections, some severe. Bacterial infections are the principal risk in patients treated with conventional therapies. Due to the relative preservation of cellular immunity early in the disease, opportunistic infections are initially uncommon. *Pneumocystis jirovecii* pneumonia and other fungal infections, listeriosis, mycobacterial infections, and respiratory syncytial and herpes virus infections occur in heavily pretreated patients receiving combination chemotherapy and as the consequence of cumulative effects of numerous therapies. Infection risk is increased following purine analogue therapy because of the side effects of myelosuppression and marked lymphopenia with T-cell depletion. The combination of purine analogues with steroids increases this infectious risk substantially. Patients with fludarabine-resistant or partially responsive disease are at highest risk of infection. The addition of rituximab, the anti-B-cell marker CD20 antibody (Chapter 94), to nucleoside analogue-based therapy does not appear to increase the risk of early or late infections, but may increase the rate of neutropenia. The addition of the anti-B- and T-cell marker CD52 antibody alemtuzumab in pretreated patients and as first-line therapy resulted in high levels of infections, particularly in nonresponders.

Active immunization with vaccines is hampered by the patient's inability to generate or retain a long and significant immune response.

Autoimmune phenomenon

Autoimmune-associated features are frequently observed in CLL. These manifestations are mainly directed against hematopoietic cells. The most common known cause of AIHA is CLL.⁶² A positive direct antiglobulin test (direct Coombs test) has been reported to be as high as 7–35% of CLL patients, and AIHA itself occurs in 10–25% of patients during the course of their disease – twice as often in patients with unmutated genes as in those with mutated ones. Tumor cells secrete small amounts of idiotypic IgM that may react with autoantigens as the Fc region of IgG, single- and double-stranded DNA, histones, cardiolipin, and other proteins. Nevertheless, in most cases autoantibodies against red blood cells are warm reactive polyclonal IgG and are not secreted by the malignant clone, but rather from normal B cells.^{49, 62} Cold agglutinins are rare. AIHA is thought to arise from the imbalance among lymphocyte subsets, contributed by therapy, which results in the emergence of the autoimmune clone. Men, aged patients, and patients with a higher lymphocyte count demonstrate a significantly higher rate of AIHA. It is usually observed in advanced stages of the disease, correlates with a poor prognosis, and has a close relationship with the activity of CLL. After therapy, 70% of patients may achieve the disappearance of the autoimmune antibodies.⁶³

ITP is observed in about 2–3% of cases, with increased megakaryocytes in the bone marrow. It should be distinguished from ITP induced by marrow infiltration, which is seen in up to 50% of patients at presentation.⁶² Two-thirds of patients with CLL-associated ITP also have AIHA (Evan's syndrome). Pure red-cell aplasia and autoantibodies against neutrophils are only rarely observed, but are part of the CLL-related autoimmune repertoire. The appearance of autoantibodies may be due to a defect of T-cell subsets controlling the autoantibody-producing B cells. This approach is supported by the observation that autoimmunity is much more common in patients treated with fludarabine, a drug known to induce profound suppression of circulating CD4 T cells.⁵⁷ Autoimmune phenomena in patients treated with purine analogues (mostly fludarabine-related) are of a more severe nature and generally trigger AIHA. However, ITP, possibly pure red-cell aplasia, and neutropenia are also seen.

Other rare entities are reported, such as paraneoplastic autoimmune disorders with connective tissue disease manifestations, including polymyositis, dermatopolymyositis, focal myositis,⁶⁴ vasculitis,⁶⁵ pemphigus vulgaris,⁶⁶ and acquired angioedema. These autoimmune disorders are related to T-cell dysfunction and may be associated with purine analogue treatment. Thirty percent of paraneoplastic pemphigus cases are reported to occur in CLL patients, as compared with other lymphoid neoplasms, and may be triggered by chemotherapy and radiotherapy.⁶² Glomerulonephritis and nephrotic syndrome are also seldom reported. These are related to different mechanisms and are marked by the presence of cryoglobulins and anti-neutrophil cytoplasmic antibodies.

Therapy of autoimmune phenomenon includes high-dose steroids and disease control.⁶³ For patients refractory to, or relapsing after, the administration of steroids, further treatment is warranted. High-dose immunoglobulins offer amelioration in some patients, but with only a transient response. Splenectomy may induce some remission, especially in patients with AIHA due to IgG alone and no complement

component. Splenic irradiation may substitute for splenectomy in older and debilitated patients.⁶² Cytotoxic agents or cyclosporine may represent valid rescue approaches. In patients where the AIHA has been triggered by fludarabine, further exposure is hazardous, although courses combining cyclophosphamide with fludarabine are much less prone to develop AIHA. Withholding treatment to patients with a positive direct antiglobulin (Coombs) test is controversial. Rituximab may be an alternative agent for the treatment of CLL-associated autoimmune diseases,⁶⁷ as well as in rare autoimmune phenomena such as pemphigus and pure red-cell aplasia.

CONCLUSION

CLL is a common indolent lymphoid neoplasm that demonstrates a wide clinical heterogeneity. It is suspected and diagnosed more commonly as an incidental finding after performance of routine blood tests. Diagnosis is made with simple immunophenotyping, but an evaluation of prognosis will likely require more extensive laboratory evaluation, including cytogenetics and molecular diagnostic techniques. The origin of CLL is yet to be elucidated, but as data accumulate, two related entities emerge, both originating from antigen-stimulated mature B lymphocytes with different clinical behavior. The complications of CLL appear to be unique to this neoplasm and are part of a failing immune system with T-cell and B-cell dysregulation. A combined immune deficiency may result, predisposing patients to recurrent infections and autoimmune diseases. New molecular and protein markers that identify patients who are at a high risk for progressive disease may provide clues for effective targeted therapies.

ACKNOWLEDGMENTS

We are grateful to Professor Debora Rund and Dr. Neta Goldschmidt for their aid in writing this chapter.

Lymphomas including Hodgkin lymphoma

Stefania Pittaluga, Martina Rudelius,
Elaine S. Jaffe

77

The classification of the malignant lymphomas has undergone significant reappraisal over the past 40 years. These changes have resulted from insights gained through the application of immunological and molecular techniques, as well as a better understanding of the clinical aspects of lymphoma through advances in diagnosis, staging, and treatment. Recently, genomic-scale gene expression profiling has been applied to lymphomas to define their molecular signatures further with the aim of improved understanding of oncogenic pathways and their clinical implications.¹ These studies have led to new prognostic and diagnostic tools and ultimately may lead to more targeted approaches to therapy.

Early classifications were based on architectural and cytological characteristics of the neoplastic elements; however, with increasing knowledge of the complexity of the immune system a more functional approach was sought. This attempt was only partially successful, owing to the limited array of tools available to the pathologist in the 1970s and 1980s. Ideally, lymphomas, like most other tumors, should be classified according to their presumed normal counterpart. This approach should provide the best information about disease biology, natural history, and response to treatment. However, there are difficulties in defining the full extent of the neoplastic clone in individual cases of lymphoma, and some well-defined lymphoma types lack obvious normal counterparts. Differentiation schemes provide useful conceptual frameworks for understanding lymphomas (Fig. 77.1), and current understanding of both the immune system and the lymphomas has been enhanced by the genomic-scale approach offered by high-throughput technologies to move towards a biologically “correct” lymphoma classification.

A more practical approach to lymphoma categorization was adopted by the International Lymphoma Study group in 1994 to define the diseases that could be recognized with the currently available morphologic, immunologic, and genetic techniques.² The resulting Revised European–American Lymphoma (REAL) classification departed from previous traditional schemes and represented a new paradigm for the classification of lymphomas. Each variant could be distinguished by a combination of morphologic, immunophenotypic, and genotypic analyses, and each was associated with a characteristic clinical behavior,

KEY CONCEPTS

LYMPHOMA

- >>> Classification consists of a list of individual disease entities defined by morphologic, immunophenotypic, genetic, and clinical features
- >>> Neoplastic cells are related to the postulated normal counterpart, when possible
- >>> Histologic grade should be applied within individual diseases
- >>> Clinical factors for individual patients, as measured by the International Prognostic Index (IPI) and gene expression profiling, are useful in predicting clinical outcome

pattern of spread, and response to therapy. In addition it stressed the distinction between histologic grade and clinical aggressiveness, and emphasized that histologic grade should be applied within individual diseases and not across the entire spectrum of lymphoid neoplasms. This classification further noted that the site of involvement (e.g., nodal versus extranodal) was often an indicator of important biologic distinctions. It stressed that many disease entities are associated with distinctive clinical presentations and natural histories, even though treatment options may still be limited.

The validity of this approach was confirmed by an international study³ concluding that the REAL classification enhanced diagnostic accuracy and reduced subjectivity. Immunophenotyping improved reproducibility and was essential in some specific entities, including most peripheral T-cell lymphomas (PTCL). This study also stressed the importance of clinical factors, such as the International Prognostic Index (IPI) for predicting prognosis and providing a guide to clinical management.⁴ Applying the IPI, a wide survival range was observed across most disease entities, suggesting that it can be misleading to stratify different diseases into risk groups based only on histologic criteria. It became evident that there was a need to approach each disease individually, considering the

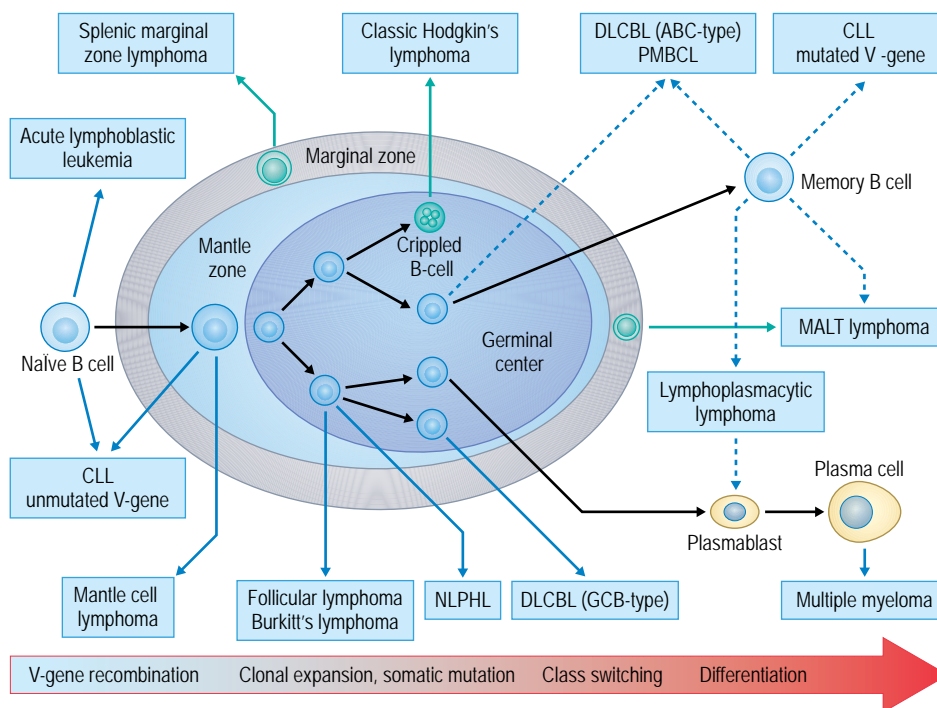

Fig. 77.1 Normal B-cell differentiation in relation to a secondary B follicle, mutational stages of the immunoglobulin genes, and cellular counterparts for B-cell lymphomas. Simplified version of B-cell development indicates points at which V-gene recombination, clonal expansion, and somatic mutations occur in relation to a secondary B follicle. B-cell lymphomas are related to different stages of B-cell differentiation and function. ABC-type, activated B-cell-like type; CLL, chronic lymphocytic leukemia/lymphoma; DLBCL, diffuse large B-cell lymphoma; GCB-type, germinal center B-cell-like type; MALT lymphoma, marginal-zone B-cell lymphoma of mucosa-associated lymphoid tissue (MALT) type; NLPHL, nodular lymphocyte-predominant Hodgkin lymphoma; PMBCL, primary mediastinal B-cell lymphoma.

KEY CONCEPTS

SOMATIC MUTATION IN RELATION TO NORMAL B-CELL DEVELOPMENT

- >> Premutational stage: circulating naïve B cells (immunoglobulin (Ig)M⁺/D⁺) prior to antigen exposure
- >> Stage of somatic mutation, clonal expansion, and isotype switch: at the germinal center
- >> Postmutational stage: selected B cells move to the periphery (postgerminal center) or to the recirculating pool (memory B cells), or undergo terminal differentiation (plasma cells)

diagnosis, the patient's risk factors, and the known idiosyncrasies of each disease with regard to treatment.

Utilizing the principles of the REAL classification, a new World Health Organization (WHO) classification for hematological malignancies was developed (Table 77.1).⁵ There are strong similarities between the WHO and REAL classification schemes. However, since

the publication of the REAL classification, new data have been generated for some categories. These studies allowed the resolution of entities that were previously listed as provisional; some were retained, whereas others were eliminated from the classification scheme. The recent application of gene expression profiling in lymphomas has generated distinct molecular "signatures" for a variety of disease entities, in some cases corresponding more closely to different stages of lymphoid differentiation, and in other instances offering insights into mechanisms of neoplastic transformation with delineation of derangements in specific pathways. This chapter focuses on the classification of neoplasms derived from mature B cells, T cells, and natural killer (NK) cells, with emphasis on malignant lymphomas.

MATURE B-CELL NEOPLASMS

LYMPHOPLASMACYTIC LYMPHOMA (LPL)

The definition of LPL is still controversial as specific genetic and immunophenotypic markers have not yet been identified. The previously used terms (lymphoplasmacytoid lymphoma, plasmacytoid lymphocytic lymphoma, or immunocytoma) do not appear to define a single

Table 77.1 Proposed World Health Organization classification for neoplastic diseases of the lymphoid tissue

B-cell neoplasms

Precursor B-cell lymphoblastic leukemia/lymphoma

Mature B-cell neoplasms

Chronic lymphocytic leukemia/small lymphocytic lymphoma

B-cell prolymphocytic leukemia

Lymphoplasmacytic lymphoma

Mantle-cell lymphoma

Follicular lymphoma

Marginal-zone B-cell lymphoma of mucosa-associated lymphoid tissue (MALT) type

Nodal marginal-zone B-cell lymphoma with or without monocytoid B cells

Splenic marginal-zone B-cell lymphoma

Hairy-cell leukemia

Diffuse large B-cell lymphoma

Subtypes: mediastinal (thymic), intravascular, primary effusion lymphoma

Burkitt's lymphoma

Plasmacytoma

Plasma-cell myeloma

T-cell neoplasms

Precursor T-cell lymphoblastic leukemia/lymphoma

Mature T-cell and natural killer (NK)-cell neoplasms

T-cell prolymphocytic leukemia

T-cell large granular lymphocytic leukemia

NK-cell leukemia

Extranodal NK/T-cell lymphoma, nasal type

Mycosis fungoides

Sézary syndrome

Angioimmunoblastic T-cell lymphoma

Peripheral T-cell lymphoma (unspecified)

Adult T-cell leukemia/lymphoma

Systemic anaplastic large-cell lymphoma (T- and null cell types)

Primary cutaneous anaplastic large-cell lymphoma

Subcutaneous panniculitis-like T-cell lymphoma

Enteropathy-type intestinal T-cell lymphoma

Hepatosplenic T-cell lymphoma

Hodgkin lymphoma (Hodgkin's disease)

Nodular lymphocyte-predominant Hodgkin lymphoma

Classic Hodgkin lymphoma

Hodgkin's lymphoma nodular sclerosis (grades I and II)

Classic Hodgkin lymphoma, lymphocyte-rich

Hodgkin lymphoma, mixed cellularity

Hodgkin lymphoma, lymphocytic depletion

More common entities are in italics.

Morphologic and clinical variants are not listed.

In this chapter we will discuss disease entities that do not appear in other chapters.

CLINICAL PEARLS

INDOLENT LYMPHOMAS

- >> Natural history: survival measured in years
- >> Least sensitive to therapy
- >> Good response to low-dose oral alkylating agents, radiotherapy, and steroids, but no curability
- >> Higher response rate and complete remission with combination of standard chemotherapy and anti-CD20 monoclonal antibody
- >> Gene expression profiling can help to identify patients who might benefit from high-dose chemotherapy and autologous stem-cell transplantation, which is a potentially curative modality

entity, as used in the literature. Many B-cell neoplasms occasionally show maturation to plasmacytoid or plasma cells containing cytoplasmic immunoglobulin (cIg), including chronic lymphocytic leukemia (CLL), and mantle-cell, follicle center, and marginal-zone cell lymphomas. We suggest that these cases be classified according to their major features, and not as LPLs. There does appear to be a distinct disorder of small lymphoid cells that show maturation to plasma cells without features of other lymphoma types, which corresponds to most cases of Waldenström's macroglobulinemia (WM). The term LPL should be restricted to these cases.

This is a disease of adult life (median age 61) that usually presents with generalized lymphadenopathy, vague constitutional symptoms, anemia, and splenomegaly. Autoimmune hemolytic anemia is a common complication. Peripheral blood involvement with an absolute lymphocytosis is less common in LPL than in B-cell CLL/small lymphocytic lymphoma. IgM monoclonal gammopathy may be associated with increased serum viscosity, leading to neurologic and vascular complications. However, this phenomenon can also be observed in other lymphomas. The course is chronic and indolent, and the disease is not generally curable with the available treatments; median survival is 78 months. Similar to other indolent lymphomas, the survival curve does not show any plateau. The treatment options, which depend on the clinical presentation, include plasmapheresis, the use of nucleoside analogues and alkylator agents, monoclonal antibody anti-CD20, either as single agents or in combination with chemotherapy⁶

The tumor consists of a diffuse proliferation of small lymphocytes, plasmacytoid lymphocytes (cells with abundant basophilic cytoplasm but lymphocyte-like nuclei), and plasma cells, with or without Dutcher bodies. The growth pattern is often interfollicular, with sparing of the sinuses.

The cells have surface and cytoplasmic Ig, usually of IgM type, usually lack IgD, and express B-cell-associated antigens (CD19, 20, 22, 79a). They are negative for CD5, CD10, and CD43; CD25 or CD11c may be faintly positive in some cases. A lack of CD5 and the presence of strong cytoplasmic Ig are useful in distinction from CLL. The postulated normal counterpart is thought to be a postfollicular medullary cord B cell based in part on the presence of somatic mutations in the Ig heavy- and light-chain variable region genes.

MANTLE-CELL LYMPHOMA (MCL)

MCL is a distinct clinicopathologic entity that has been more precisely defined in recent years through the integration of immunophenotypic, molecular genetic, and clinicopathologic studies. This tumor was recognized in the Kiel classification as centrocytic lymphoma and in the modified Rappaport scheme as lymphocytic lymphoma of intermediate differentiation. It tended to surround residual naked germinal centers, and a derivation from the follicular lymphoid cuff was postulated. Tumors with a very conspicuous mantle-zone pattern of growth were also termed 'mantle-zone lymphoma.'

MCL occurs in adults (median age 62), with a high male-to-female ratio. Most patients present with advanced-stage disease at diagnosis. Common sites of involvement include the lymph nodes, spleen, bone marrow, and lymphoid tissue of Waldeyer's ring. Gastrointestinal tract involvement is common and is associated with the picture of lymphomatous polyposis. This tumor appears to be incurable with the available treatments. In data collated from several retrospective studies the prognosis is poor, with a median survival ranging from 20 months to over 52 months. The relapse rate is high, with a median disease-free survival between 10.2 and 25.5 months.^{7, 8} The clinical course and survival can be better predicted by gene expression profiling.⁹ Genes whose expression is associated with short survival belong to the proliferation signature and are involved in cell cycle progression and DNA synthesis. The proliferation signature provides a quantitative measurement of tumor proliferation rate and can be used to get valuable prognostic information. The central role of proliferation was also stressed in the past by several studies based on scoring of Ki67-positive cells^{10, 11}; however, the larger set of genes analyzed by expression profiling offers a more accurate survival stratification compared with a single marker.

It is important to identify at diagnosis those patients who may benefit from a more aggressive therapy versus those with a more indolent clinical disease who may be observed on a watchful waiting protocol. The treatment approach to newly diagnosed patients with MCL depends on the patient's eligibility for stem-cell transplantation (STC). However, because of the frequent bone marrow involvement, purging of the neoplastic cells is difficult to achieve.¹² With the addition of rituximab to standard chemotherapy regimens, an overall response rate of 94% and high rate of clinical remission can be achieved, but this does not yet

translate in a prolonged progression-free survival. Therefore new therapeutic strategies, including molecular targeting agents like proteasome inhibitors such as bortezomib, are under investigation.¹³

The hallmark of MCL is a monotonous cytologic composition. In the typical case the cells are slightly larger than a normal lymphocyte, with finely clumped chromatin, scant cytoplasm, inconspicuous nucleoli, and irregular nuclear contour. Cytological (blastoid or blastic) and architectural variants (mantle zone, nodular, and diffuse) have been described and associated with a more aggressive clinical course (blastoid variant) or with a longer median survival (mantle-zone pattern). However, because of the overall poor prognosis and the lack of statistical significance of these architectural/cytological changes, the WHO classification considers MCL and its variants to be one group.⁵

Immunophenotypic and genotypic studies have been helpful in precisely defining MCL. The immunophenotype is distinctive (IgM/IgD⁺; CD5⁺, CD10⁻, and CD23⁻). In addition, the chromosomal translocation t(11;14) involving *CYCLIN D1* located at the *BCL-1/PRAD1* locus is associated with MCL, but is absent in most other low- and high-grade B-cell malignancies. By Northern analysis virtually 100% of cases of MCL have shown overexpression of cyclin D1, which has not been identified to the same degree in other B-cell malignancies. Cyclin D1 overexpression is believed to be essential in the pathogenesis of MCL; however, a few cases with similar clinical course and gene expression signature that did not overexpress Cyclin D1 have recently been identified.¹⁴ Interestingly, they expressed either Cyclin D2 or Cyclin D3, which may substitute for Cyclin D1 in the pathogenesis of MCL. Additional alterations involving other cell cycle regulatory molecules (RB, p53, CDK inhibitors) have been described in the more aggressive forms of MCL. The INK4a/ARF deletions occur in approximately 20% of cases. The INK4a/ARF locus encodes two key suppressor genes, p16^{INK4a} and p14^{ARF}, which are important negative cell cycle regulators.

The postulated normal counterpart is the CD5⁺ "virgin" B cell, sIgM⁺ and sIgD⁺, that can be found in the peripheral blood and in the mantle of reactive germinal centers.

FOLLICULAR LYMPHOMA (FL)

FL is the most common subtype of non-Hodgkin lymphoma in the USA and accounts for approximately 45% of all newly diagnosed cases. It has a peak incidence in the fifth and sixth decades, and is rare under the age of 20. Men and women are equally affected: FL is found less commonly in African-American and Asian populations. Most patients have stage 3 or 4 disease at diagnosis, with generalized lymphadenopathy and staging evaluation that usually reveals bone marrow involvement. Approximately 10% of patients have circulating malignant cells. However, careful immunophenotypic or molecular analyses may disclose peripheral blood involvement in a higher proportion of patients.

FL is indolent, but currently incurable with available therapeutic modalities. The natural history of the disease, with frequent relapses and relatively long survival, has led to different therapeutic approaches (watchful waiting versus chemotherapy).¹⁵ Several attempts have been made to design predictive models to identify patients for whom aggressive, experimental therapies are warranted. Clinical parameters have been successfully used to develop prognostic indexes (for example, the FLIPI, adjusted from the IPI for aggressive B-cell lymphoma)¹⁶; however, the prognostic assessment of patients with FL could be improved by including other biological variables, like gene expression signatures or

CLINICAL PEARLS

AGGRESSIVE LYMPHOMAS

- >> Natural history: survival measured in months
- >> Successful therapy can be achieved with combination chemotherapy
- >> Relapses from chemotherapy-induced remission may be cured with high-dose chemotherapy with hematopoietic support
- >> In addition to the International Prognostic Index (IPI), gene expression profiling can be useful in predicting prognosis and survival of individual patients

immunohistochemistry, taking into account the environment and infiltrating inflammatory cells.^{17,18}

More recently, new therapeutic avenues have been explored as, following relapses, patients become resistant to chemotherapy. A more aggressive approach with intent to eradicate the disease at the first or second relapse has been tested in clinical trials.¹⁹ The use of monoclonal antibody therapies (especially anti-CD20), either as carriers of toxins or radioisotopes or as direct cytotoxic agents, has opened a new era in the treatment of B-cell lymphomas. The addition of anti-CD20 to conventional chemotherapy (cyclophosphamide, doxorubicin, vincristine and prednisone [CHOP] versus CHOP-rituximab [R]) has improved both remission and duration rates.²⁰

The natural history of the disease is associated with histologic progression in both pattern and cell type (Fig. 77.2). A heterogeneous cytologic composition is one of the hallmarks of FL. Usually, all of the follicle center cells are represented, but in varying proportions.

This variation in cytologic composition is the basis for the subclassification of FL. It should be stressed that the variation in cytologic grade is a continuum, and therefore precise morphologic criteria for subclassification are difficult to establish. Most studies have shown that the subclassification of FL is difficult to reproduce among groups of pathologists. According to the WHO clinical advisory committee, FL should be graded and for most clinical purposes the distinction into two grades is sufficient (grade 1, predominantly small cleaved cell together with grade 2, mixed small cleaved and large cell; as distinct from grade 3, predominantly large cell). However, the distinction into three grades continues, with a recommendation for the use of the Berard counting method.⁵

The vast majority of FL (approximately 90%) are associated with a t(14;18) involving rearrangement of the *BCL2* gene. This translocation appears to result in constitutive expression of BCL-2 protein, which is capable of inhibiting apoptosis in lymphoid cells. The cells of FL accumulate and are at risk for secondary mutations, which may be associated with

histologic progression. It is interesting that the small subset of grade 3 FL (large cell) is less commonly associated with the *BCL2* translocation. Thus, some forms of FL may have a different pathogenesis. It is thought that the *BCL2* translocation occurs at a very early stage of B-cell development, during immunoglobulin gene rearrangement. This fact may contribute to the difficulty of eradicating the neoplastic clone with chemotherapy.

Most FL present in lymph nodes while a subset of cases with the morphologic features of FL present in extranodal sites. When these tumors are localized (without lymph node involvement) they usually have a good prognosis. Complete remissions may be obtained with either surgical excision or local radiation therapy. In particular cutaneous follicle center lymphoma, which frequently lacks the *BCL2* translocation and *BCL2* expression, is considered by the European Organization for the Research and Treatment of Cancer (EORTC)-WHO classification as a separate entity.²¹ However, when *BCL2* expression is detected, the possibility that this may represent a secondary site of involvement should be considered. FL in children is also often extranodal at presentation²² and usually of large-cell type (grade 3), suggesting an alternate molecular pathogenesis.²³

The cells have a mature B-cell phenotype with expression of the B-cell antigens CD19, CD20, and CD22. Surface Ig is positive, most commonly with IgM expression, but IgG or IgA can be seen in many cases. CD10, BCL-6 stains are positive, but CD5 is negative.

FL represents the neoplastic counterpart of the reactive germinal center cells. Consistent with their normal counterparts, intracлонаl heterogeneity with high numbers of somatic mutations and ongoing mutations of the Ig genes was detected in the neoplastic cells.²⁴

MARGINAL-ZONE B-CELL LYMPHOMA OF MUCOSA-ASSOCIATED LYMPHOID TISSUE (MALT) TYPE

Most lymphomas of marginal-zone derivation present in extranodal sites and have histopathologic and clinical features that are part of the spectrum of MALT lymphomas. MALT lymphomas are characterized by a heterogeneous cellular composition that includes marginal-zone or centrocyte-like cells, monocytoid B cells, small lymphocytes, and plasma cells. In most cases large transformed cells are uncommon, but reactive germinal centers are nearly always present. Therefore, it is not surprising that, based on the heterogeneous cellular composition and the presence of reactive follicles, most MALT lymphomas were in the past diagnosed as pseudolymphomas or atypical hyperplasias. However, recent studies have shown the majority to be composed of monoclonal B cells. When follicular colonization by the neoplastic cells occurs the process can simulate FL.

MALT lymphomas have been described in nearly every anatomic site, but are most frequent in the stomach, lung, thyroid, salivary gland, and lacrimal gland. Other less common sites of involvement include the orbit, breast, conjunctiva, bladder, kidney, and thymus. Most patients present with localized disease, although regional lymph node involvement is common in gastric and salivary gland MALT lymphoma. Widespread nodal involvement is infrequent, as is bone marrow involvement. The clinical course is usually quite indolent and many patients are asymptomatic. MALT lymphomas tend to relapse in other MALT-associated sites.

MALT lymphomas of the salivary gland and thyroid are usually associated with a history of autoimmune diseases. There is a strong association between chronic infection with *Helicobacter pylori* and

Fig. 77.2 Follicular lymphoma. The neoplastic follicles are similar in size and are partially surrounded by lymphoid cuffs. In contrast to reactive germinal centers, they lack polarization and tingible body macrophages ('starry-sky pattern').

gastric MALT, which is considered an etiologic agent. Other infectious agents have been described in MALT lymphomas involving skin (*Borrelia burgdorferi*), ocular adnexae (*Chlamydia psittaci*), and small intestine (*Campylobacter jejuni*); however, a causal relationship has not yet been demonstrated. Chronic antigen stimulation is critical to both the development of a MALT lymphoma and the maintenance of the neoplastic state.²⁵ Indeed, in some cases antibiotic therapy and the eradication of *H. pylori* has led to the spontaneous remission of gastric MALT lymphoma.²⁶ Antibiotic treatment is currently advocated as first-line therapy. However, the therapy of MALT lymphomas remains controversial. Isolated lesions readily amenable to surgical excision should be removed. Systemic chemotherapy may be warranted for more widespread disease, and local radiation therapy may play a role in the control of localized tumor masses, especially for gastric and orbital MALT lymphomas.

Immunophenotyping is helpful in the differential diagnosis of MALT lymphomas from cytologically similar lymphomas such as B-cell chronic lymphocytic leukemia/small lymphocytic lymphoma (B-CLL/SLL) and MCL. MALT lymphomas are positive for B-cell-associated antigens CD19, CD20, and CD22, but are negative for CD5 and CD10. BCL-6 and CD10 are helpful markers to identify residual reactive germinal center cells.

MALT lymphomas also have several recurring cytogenetic abnormalities, including t(11;18)(q21;q21), t(1;14)(p22;q32), t(14;18)(q32;q21), t(3;14)(q27;q32), and t(3;14)(p14.1;q32), which are observed with variable frequency, often depending upon the anatomical site.²⁷ Although several genes are involved in these translocations, at least three of them – t(11;18), t(1;14) and t(14;18) – share a common pathway, which leads to the activation of NF-κB and its downstream targets.²⁷

The translocation t(11;18)(q21;q21) is associated exclusively with low-grade extranodal MALT and is not detected in cases with simultaneous low- and high-grade tumors, or in primary extranodal large-cell lymphomas, raising the question of whether these primary extranodal lymphomas are in fact related to low-grade MALT. In the WHO Clinical Advisory Committee, the term extranodal marginal-zone lymphoma (MZL) of MALT type applies only to low-grade MALT, and it was recommended that the term high-grade MALT not be used for extranodal large-cell lymphomas in a MALT site. The putative cell of origin of MZL is a memory B cell (postgerminal center).

NODAL MARGINAL-ZONE LYMPHOMA WITH OR WITHOUT MONOCYTOID B CELLS

Monocytoid B-cell lymphoma is seen most often in association with an extranodal MALT lymphoma. However, the existence of the primary extranodal disease may not be immediately apparent. Relapses in nodal sites can occur many years after the primary diagnosis. Patients who present with nodal disease, often with bone marrow involvement and no evidence of extranodal disease, tend to have a more aggressive clinical course than those with extranodal MALT.⁵

The neoplastic proliferation is mostly composed of monocytoid B cells with interspersed large blast-like cells. Immunophenotype is similar to that of other marginal-zone B-cell lymphomas, CD20+, CD5⁻ CD10⁻, with variable IgD expression (weak to negative). Some nodal MZL have a morphology and immunophenotype similar to those of splenic marginal zone (see below) and in these cases the tumor cells are IgD-positive.²⁸

CLINICAL PEARLS

HIGHLY AGGRESSIVE LYMPHOMAS

- >> More common in children
- >> Natural history similar to acute leukemia
- >> Successful treatment includes high-dose chemotherapy (induction, consolidation, and maintenance phases) with central nervous system prophylaxis

SPLENIC MARGINAL-ZONE LYMPHOMA

Splenic MZL (SMZL) present in adults and are slightly more common in women than in men. The clinical presentation is splenomegaly, usually without peripheral lymphadenopathy. The majority of patients have bone marrow involvement, but there is usually only a modest lymphocytosis, with elevations in the lymphocyte count usually less than in B-CLL. Some evidence of plasmacytoid differentiation may be seen and patients may have a small M protein. The abundant pale cytoplasm evident in tissue sections may also be seen in peripheral blood smears. The cytologic features may be mistaken for those of hairy-cell leukemia. The disorder described as splenic lymphoma with villous lymphocytes (SLVL) appears equivalent to SMZL.²⁹ The course is reported to be indolent, and splenectomy may be followed by a prolonged remission.

Immunophenotypic studies are useful in distinguishing SMZL from CLL/SLL involving the spleen. Whereas typical CLL/SLL cells are CD5⁺, SMZL cells are CD5⁻. Careful attention to the cytologic features in these cases indicates that the cells have somewhat more abundant cytoplasm than those of typical CLL/SLL. Histologically, the spleen shows expansion of the white pulp, but usually some infiltration of the red pulp is present as well. A characteristic biphasic pattern in the neoplastic white pulp has been described²⁹ in which a central zone of small lymphocytes is surrounded by a peripheral zone of larger cells that resemble marginal-zone cells. In this instance the residual polytypic mantle is no longer present. The phenotype of these cells resembles that of the other marginal-zone B-cell lymphomas; however, sIgD expression is more frequently positive. Deletion of 7q31 has been described in SMZL. Studies of the Ig variable genes have also revealed the presence of somatic mutations, suggesting a postfollicular origin; however, similar to CLL cases, a more complex picture with cases of SMZL lacking somatic mutations has been reported.³⁰

DIFFUSE LARGE B-CELL LYMPHOMA (DLBCL)

DLBCL is one of the more common subtypes of non-Hodgkin lymphoma, representing up to 40% of cases. It has an aggressive natural history but responds well to chemotherapy. The complete remission rate with modern regimens is 75–80%, with long-term disease-free survival approaching 50% or more in most series.³¹ This lymphoma may present in lymph nodes or in extranodal sites, including bone, skin, thyroid, gastrointestinal tract, and lung.

This represents one of the most heterogeneous categories in the WHO classification, in terms of morphology and phenotype.⁵ Because of the variation in the response to chemotherapy and the frequency of

DLBCL, there has been great interest in identifying morphologic or immunophenotypic features that might be prognostically important. To address these issues, which were traditionally not resolved by morphology and phenotype, DLBCL was among the first lymphomas to be analyzed by cDNA microarray.^{32,33} Three groups were identified based on the differential expression of a large set of genes, namely germinal center-like group (GCB), activated B-cell-like group (ABC), and primary mediastinal B-cell lymphoma (PMBCL).^{32,34,35} GCB DLBCLs express a set of genes that are associated with normal germinal center B cells, whereas ABC DLBCLs show downregulation of these genes and share similarities with postgerminal center B cells. A unique signature was identified by gene expression profiling in PMBCL^{34,35} and shared similarities with Hodgkin lymphoma (HL) cell lines, including constitutive activation of the NF- κ B and recurrent gains and amplification of c-Rel.³⁶

The t(14;18) translocation involving BCL-2 and immunoglobulin heavy-chain gene has been detected in the GCB and to lesser extent in PMBCL, but not in the ABC. By contrast, ABC cases express high levels of BCL-2 protein due to gene amplification and not to the BCL-2 translocation.³⁷ Indeed, previous studies have also shown reduced disease-free survival in cases of DLBCL with overexpression of BCL-2 (irrespective of the presence of the translocation). Gene expression profiling identified differences in outcome in patients treated with anthracycline-based chemotherapy regimens, particularly between GCB and ABC subtypes (with a 5-year survival rate of 59% and 31% respectively),³² while PMBCL behaved similarly to the GCB group, with a 5-year survival rate of 64%.³⁴ This stratification is statistically independent of the IPI in predicting survival, and therefore probably reflects true biological differences. However, not all heterogeneity can be explained based on expression profiling; clinical factors also have an impact on survival, as shown by the IPI stratification of patients with aggressive lymphomas.⁴

DLBCL are composed of large transformed lymphoid cells with nuclei at least twice the size of a small lymphocyte (Fig. 77.3). The nuclei generally have vesicular chromatin, prominent nucleoli, often membrane-bound, and basophilic cytoplasm resembling centroblasts with a moderate to high proliferation fraction. Marked variation in the nuclear contour can be seen. Most aggressive lymphomas show a spectrum in cytologic appearance, and in any given field the predominant cell could be centroblasts or immunoblasts. The designation of immunoblastic lymphoma of B-cell type is controversial and poorly reproducible among observers. Although there is no correlation between morphology and gene expression profiling, the majority of centroblastic DLBCL falls into the GCB group, and the majority of immunoblastic into the ABC group. Algorithms based on immunophenotype have been proposed as surrogates for cDNA microarray using CD10/BCL-6 positivity for GCB and Mum-1/IRF-4 for ABC with the addition of BCL-2 in combination with IPI and could improve the stratification of DLBCL. However, there is as yet no consensus for the best model to address the heterogeneity of DLBCL.^{38–40}

Some large B-cell lymphomas are rich in either small T lymphocytes or histiocytes or both. Histologically, they can resemble PTCL or Hodgkin disease (HD).⁴¹ They are clinically aggressive, with a prognosis comparable to that of DLBCL. The admixture of small lymphocytes and histiocytes is a variable phenomenon, and the inflammatory background can be absent on second biopsies. T-cell-rich B-cell lymphoma, as currently defined, does not appear to be a distinct clinical pathologic entity but rather a variant that can be seen in association with several different

Fig. 77.3 Diffuse large-cell lymphoma. The neoplastic cells have large round to oval nuclei with vesicular chromatin and multiple eosinophilic nucleoli. Numerous mitoses are also present.

subtypes of DLBCL.⁵ Although histiocyte-rich large B-cell lymphoma has a more aggressive clinical behavior, it tends to occur in younger patients compared to other DLBCL, and often presents with advanced stage and bone marrow involvement.

PMBCL has emerged in recent years as a distinct clinicopathologic entity.⁵ However, there are no reliable criteria to separate PMBCL from DLBCL morphologically or phenotypically. The diagnosis is usually made by a constellation of clinical and morphological features. PMBCLs cytologically resemble many other large B-cell lymphomas. A constant feature is relatively abundant pale cytoplasm, often with distinct cytoplasmic membranes. Many cases have fine compartmentalizing sclerosis, which can even lead to misdiagnosis as an epithelial tumor, such as thymoma. The tumor appears to be derived from medullary B cells within the thymus gland. These cells express CD20 and CD79a, but not surface Ig. Recently, the expression of the *MAL* gene has been detected in PMBCL and not in other DLBCL.⁴² Clinically, PMBCL shows marked female predominance. It is common in adolescents and young adults, with a median age at presentation in the fourth decade. The clinical presentation is that of a rapidly growing anterior mediastinal mass with frequent superior vena cava syndrome and/or airway obstruction. Nodal involvement is uncommon at presentation and also at relapse. Frequent extranodal sites of involvement, particularly at relapse, include the liver, kidneys, adrenal glands, ovaries, gastrointestinal tract, and central nervous system. Earlier studies suggested that the tumor was associated with an unusually aggressive clinical course, with poor responses to conventional chemotherapy. More recent studies have reported cure rates better than those seen for other large B-cell lymphomas with the use of combined chemotherapy, while the use of radiation remains controversial.⁴³

It is of interest that PMBCL exhibits many clinicopathologic similarities with classic HL, nodular sclerosis subtype. Gray-zone lymphomas with features intermediate between these two entities have also been described.^{44,45} Gene expression profiling studies reported by two independent groups have supported a close relationship between

PMLBCL and classic HL.^{34,35} TRAF1 expression and c-REL amplification are seen in both types of neoplasms and can be detected with suitable immunohistochemical studies.⁴⁶

BURKITT LYMPHOMA (BL)

BL is most common in children and accounts for up to one-third of all pediatric lymphomas in the USA.⁴⁷ It is the most rapidly growing of all lymphomas, with 100% of the cells in cell cycle at any time. It usually presents in extranodal sites. In nonendemic regions, such as the USA, common sites of presentation are the ileocecal region, ovaries, kidneys, or breasts. Jaw presentations, as well as the involvement of other facial bones, are common in African or endemic cases and are occasionally seen in nonendemic regions. Bone marrow involvement is a poor prognostic sign.

BL is one of the more common tumors associated with the human immunodeficiency virus (HIV).⁴⁸ It can present at any time during the clinical course. In some patients with HIV infection BL is the initial acquired immunodeficiency syndrome (AIDS)-defining illness.

The pathogenesis of BL is undoubtedly related to the translocations involving the *c-MYC* oncogene, which are seen in virtually 100% of cases. Most of the translocations involve the Ig heavy-chain gene on chromosome 14. Less commonly the light-chain genes on chromosomes 2 and 22 are involved. African BL occurs in regions endemic for malaria, and it has been postulated that immunosuppression associated with malarial infection puts patients at increased risk. In this regard, the pathogenesis appears similar to that seen with HIV infection.

Epstein-Barr virus (EBV) is closely linked to BL in endemic regions but is less frequently seen (15–20%) in Europe and North America.⁴⁷ In other regions, characterized by low socioeconomic status and EBV infection at an early age, BL is often EBV-positive, in the range of 50–70%. These data support the concept the EBV is a cofactor for the development of BL. Differences in the proportion of cases associated with the two EBV strains (types 1 and 2) have also been shown in sporadic and endemic EBV-positive BL.

Cytologically, BL is monomorphic with cells of medium size, round nuclei, and multiple (2–5) basophilic nucleoli. The cytoplasm is deeply basophilic and moderately abundant. These cells contain cytoplasmic lipid vacuoles, which are probably a manifestation of the high rates of proliferation and spontaneous cell death. The starry-sky pattern characteristic of BL is a manifestation of the numerous benign macrophages that have ingested karyorrhectic or apoptotic tumor cells.

BL has a mature B-cell phenotype. The cells express CD19, CD20, CD22, CD79a, and monoclonal surface Ig, nearly always IgM. CD10 is positive in nearly all cases, and CD5, CD23, and BCL-2 are consistently negative.

T-CELL AND PUTATIVE NK-CELL NEOPLASMS

OVERVIEW OF THE CLASSIFICATION OF T-CELL NEOPLASMS

Whereas the definition of precursor T-cell or lymphoblastic neoplasms is straightforward, the classification of PTCL has been controversial. These are uncommon, representing fewer than 15% of all non-Hodgkin

lymphomas. Most previously published classification schemes for the malignant lymphomas in the USA or Europe have been based on the far more common B-cell malignancies. In addition, the molecular pathogenesis of most peripheral T-cell neoplasms has not been defined, and immunophenotypic markers are less specific for apparently distinct disease entities. For these reasons, the WHO classification relies to a considerable extent on clinical presentation to subdivide these tumors.⁵

EXTRANODAL NK/T-CELL LYMPHOMA, NASAL-TYPE

Extranodal NK/T-cell lymphoma, nasal type, is a distinct clinicopathologic entity highly associated with EBV. It is much more common in Asians than in those of European background. Clusters of the disease have also been reported in Central and South America in individuals of Native American heritage, suggesting that ethnic background may play a role in the pathogenesis of these lymphomas. It affects adults (median age 50) and the most common clinical presentation is a destructive nasal or midline facial lesion. Palatal destruction, orbital swelling, and edema can be prominent. NK/T-cell lymphomas have been reported in other extranodal sites, including the skin, soft tissue, testis, upper respiratory tract, and gastrointestinal tract. A leukemic form of the disease has also been reported, with similar morphologic, immunophenotypic, and genotypic features. The clinical course is usually aggressive, with a slightly improved median survival in patients with localized disease. However, with current chemotherapy the outcome remains poor. Radiation therapy may be effective in localized disease.⁴⁹

Extranodal NK/T-cell lymphoma, nasal type, is characterized by a broad cytologic spectrum. The atypical cells can be small or medium in size. Large atypical and hyperchromatic cells can be admixed, or may predominate. If the small cells are in the majority the disease can be difficult to distinguish from an inflammatory or infectious process. In early stages there can also be a prominent admixture of inflammatory cells, causing further difficulty in diagnosis.

Although the cells express some T-cell-associated antigens, most commonly CD2, other T-cell markers, such as surface CD3, are usually absent. Cytoplasmic CD3 can be found in paraffin-embedded sections, but cytoplasmic CD3 can be found in NK cells and is not specific for a T-cell lineage tumor. In addition, molecular studies have not shown a clonal T-cell gene rearrangement, despite clonality being shown by other methods.⁵⁰ In favor of an NK-cell origin, the cells are nearly always CD56⁺, although CD16 and CD57 are usually negative. EBV is invariably positive by *in situ* hybridization.

A hemophagocytic syndrome is a common clinical complication, and adversely affects survival in extranodal NK/T-cell lymphoma, nasal type. It is likely that EBV plays a role in the pathogenesis of the hemophagocytic syndrome.

ANGIOIMMUNOBLASTIC T-CELL LYMPHOMA (AITL)

AITL was initially proposed as an abnormal immune reaction or form of atypical lymphoid hyperplasia with a high risk of progression to malignant lymphoma. Because the majority of cases show clonal rearrangements of T-cell receptor genes, it is now regarded as a variant of T-cell lymphoma. The median survival is usually less than 5 years,

so that the designation as lymphoma is also warranted on clinical grounds.

The nodal architecture is generally effaced, but peripheral sinuses are often open and even dilated. Often regressed follicles containing a proliferation of dendritic cells and blood vessels (so-called 'burned-out') are present and only rarely hyperplastic follicles are noted. At low power there is usually a striking proliferation of postcapillary venules with prominent arborization. Clusters of atypical lymphoid cells with clear cytoplasm may be seen and they are admixed with an inflammatory cellular background containing small lymphocytes, immunoblasts, plasma cells, and histiocytes, with or without eosinophils. The abnormal cells are T cells usually positive for CD4 and CD10; this phenotype has been described in a particular subtype of T-helper cells associated with the germinal centers. More recently CXCL-13, a chemokine involved in B-cell trafficking into the germinal centers, has been described in AILT.^{51, 52} These markers provide support for T-helper cell derivation of this lymphoma and also offer powerful diagnostic tools. Another helpful diagnostic feature is the presence of numerous CD21⁺ dendritic reticulum cells, which are especially prominent around postcapillary venules. Polyclonal plasma cells may be numerous.

AILT presents in adults; most patients have generalized lymphadenopathy with prominent systemic symptoms, including fever, weight loss, and skin rash. There is usually a polyclonal hypergammaglobulinemia. Patients may initially respond to steroids or mild cytotoxic chemotherapy, but progression usually occurs. More aggressive combination chemotherapeutic regimens have led to a higher remission rate but patients are prone to secondary infectious complications. Progression to a more monomorphic T-cell immunoblastic lymphoma occurs in some cases, and the proportion of large immunoblastic cells appears to correlate with the clinical course. Rarely, B-cell immunoblastic lymphomas positive for EBV occur in patients with AILT; these latter malignancies appear secondary to the underlying immunodeficiency.

PERIPHERAL T-CELL LYMPHOMAS, UNSPECIFIED

PTCL is a diagnosis of exclusion and is admittedly a heterogeneous category with most cases being nodal in origin. PTCL are characterized by a heterogeneous cellular composition. There is usually a mixture of small and large atypical lymphoid cells. An inflammatory background is common, consisting of eosinophils, plasma cells, and histiocytes. If the epithelioid histiocytes are numerous and clustered, the neoplasm fulfills the criteria for lymphoepithelioid cell lymphoma or Lennert's lymphoma, which is considered in the WHO to be a morphologic variant of PTCL and not a distinctive clinicopathologic entity.

Clinically, PTCL most often present in adults. Most patients exhibit generalized lymphadenopathy, hepatosplenomegaly, and frequent bone marrow involvement. Constitutional symptoms, including fever and night sweats, are common, as is pruritus. The clinical course is aggressive, although complete remissions may be obtained with combination chemotherapy.⁵³ However, the relapse rate is higher in PTCL than in B-cell lymphomas of comparable histologic grade.⁵³

PTCL, as defined in the WHO classification, remains heterogeneous. It is likely that individual clinicopathologic entities will be delineated in the future from this broad group of malignancies. Thus far,

immunophenotypic criteria have not been helpful in delineating subtypes. Most cases have a mature T-cell phenotype and express one of the major subset antigens, with CD4 expression seen more frequently than CD8. These are not clonal markers, and antigen expression can change over time. Loss of one of the pan-T-cell antigens (CD3, CD5, CD2, or CD7) is seen in 75% of cases, with CD7 most frequently being absent.

SYSTEMIC, ANAPLASTIC LARGE-CELL LYMPHOMA (ALCL)

ALCL is characterized by pleomorphic or monomorphic cells that have a propensity to invade lymphoid sinuses. Because of the sinusoidal location of the tumor cells and their lobulated nuclear appearance, this disease was previously interpreted as a variant of malignant histiocytosis. Misdiagnosis as metastatic carcinoma or melanoma was also common.

A consistent feature is the expression of the CD30 antigen, which is a hallmark of this disease. It has been referred to as Ki-1-positive lymphoma. However, CD30 expression is not specific for ALCL and may also be seen in other forms of malignant lymphoma, including HD. Systemic ALCL is associated with a characteristic chromosomal translocation, t(2;5)(p23;q35), involving *ALK/NPM* genes, respectively.⁵⁴ A variety of other partners of ALK has been identified and monoclonal antibodies to the cytoplasmic portion of ALK protein have been made, and are able to identify tumor cells regardless of the underlying translocation.⁵⁵

The cells of classic ALCL have large, often lobulated nuclei with small basophilic nucleoli. In some cases the nuclei may be round. The cytoplasm is usually abundant and amphophilic, with distinct cytoplasmic borders. A prominent Golgi region is generally visible. Immunohistochemistry is very valuable in the correct diagnosis of ALCL. The prominent Golgi region usually shows intense staining for CD30 and epithelial membrane antigen (EMA). In the majority of cases the neoplastic cells show nuclear and cytoplasmic staining with antibodies to the ALK protein. In about 15–20% of cases the presence of only cytoplasmic staining for ALK suggests that a variant translocation has occurred.⁵⁶

The cells exhibit an aberrant phenotype with loss of many of the T-cell-associated antigens. Both CD3 and CD45RO, the most widely used pan-T-cell markers, are negative in more than 50% of cases. CD2 and CD4 are positive in the majority of cases, whereas CD8 is usually negative. ALCL cells, despite the CD4⁺/CD8⁻ phenotype, do express the cytotoxic-associated antigens TIA-1, granzyme B, and perforin.⁵⁷ In addition clusterin is generally present in ALCL and represents another useful diagnostic marker.⁵⁸ Molecular studies in most cases demonstrate T-cell receptor rearrangement, confirming a T-cell origin.

ALCL is most common in children and young adults. However, in elderly patients the t(2;5) or ALK expression is lacking, suggesting that these cases may be part of a different clinicopathologic entity. A marked male predominance, usually presenting with nodal disease, has been noted. However, a high incidence of extranodal site involvement has also been reported (involving skin, bone and soft tissue). About 75% of cases present with advanced stage and systemic symptoms.⁵⁹ Although these lymphomas have an aggressive natural clinical history they respond well to chemotherapy; overall survival and disease-free

survival are significantly better in ALK⁺ than in ALK⁻ cases.⁵⁹ Recent studies suggest that the IPI is prognostically useful, in contrast to early reports.⁵⁹

PRIMARY CUTANEOUS ANAPLASTIC LARGE-CELL LYMPHOMA

A primary cutaneous form of ALCL is closely related to lymphomatoid papulosis and differs clinically, immunophenotypically, and at the molecular level from the systemic form.⁶⁰ Indeed, lymphomatoid papulosis and cutaneous ALCL appear to represent a histologic and clinical continuum of CD30⁺ cutaneous lymphoproliferative diseases. Small lesions are likely to regress, whereas patients with large tumor masses may develop disseminated disease with lymph node involvement. However, primary cutaneous ALCL is a more indolent disease than other T-cell lymphomas of the skin. Most patients with primary cutaneous ALCL have multiple skin lesions. Because the skin nodules may show spontaneous regression, a period of observation is usually warranted before the institution of any chemotherapy.⁶¹ Cutaneous ALCL is CD30⁺, but usually ALK-1- and EMA-negative, and also lacks the t(2;5) translocation.⁶⁰

SUBCUTANEOUS PANNICULITIS-LIKE T-CELL LYMPHOMA

Subcutaneous panniculitis-like T-cell lymphoma is sufficiently distinct to warrant separation from other forms of peripheral T-cell lymphoma.⁶² The disease usually presents with subcutaneous nodules, primarily affecting the extremities and ranging in size from 0.5 cm to several centimeters in diameter. Larger nodules may become necrotic. In its early stages the infiltrate may appear deceptively benign, and lesions are often misdiagnosed as panniculitis.⁶² However, histologic progression usually occurs and subsequent biopsies show more pronounced cytologic atypia, permitting the diagnosis of malignant lymphoma.

The cytologic composition of subcutaneous panniculitis-like T-cell lymphoma varies. The lesions may contain a predominance of small to medium-sized lymphoid cells with clear cytoplasm, or larger cells with hyperchromatic nuclei. Admixed reactive histiocytes are frequently present, particularly in areas of fat infiltration and destruction. The histiocytes are frequently vacuolated, owing to ingested lipid material. Vascular invasion is seen in some cases, and necrosis and karyorrhexis are common.

The neoplastic cells are CD8⁺ cytotoxic T cells that are also positive for the cytotoxic proteins perforin, granzyme B, and TIA-1. These proteins may be responsible for the cellular destruction seen in these tumors.

A hemophagocytic syndrome is a frequent complication of subcutaneous panniculitis-like T-cell lymphoma.⁶² Patients present with fever, pancytopenia, and hepatosplenomegaly. It is most readily diagnosed in bone marrow aspirate smears, where histiocytes containing erythrocytes, platelets, and other blood elements may be observed. The hemophagocytic syndrome usually heralds a fulminant downhill clinical course. However, if therapy for the underlying lymphoma is instituted and is successful, the hemophagocytic syndrome may remit. A hemophagocytic syndrome is the cause of death in the majority of patients with subcutaneous panniculitis-like T-cell lymphoma.

Dissemination to lymph nodes and other organs is uncommon and usually occurs late in the clinical course. The cause of the hemophagocytic syndrome appears to be related to cytokine production by the malignant cells, including interferon- γ , granulocyte-monocyte colony-stimulating factor and macrophage inflammatory protein-1 α (MIP-1 α).

It is likely that subcutaneous panniculitis-like T-cell lymphoma is the process previously described as histiocytic cytophagic panniculitis. It had been thought that histiocytic cytophagic panniculitis was a malignant histiocytic proliferation. Although histiocytes may be numerous in these lesions, the malignant cells have a mature T-cell phenotype. Evidence for an association with EBV has been lacking.

ENTEROPATHY-TYPE T-CELL LYMPHOMA (ETL)

ETL was originally termed malignant histiocytosis of the intestine.⁶³ However, the demonstration of clonal T-cell gene rearrangement indicated that it was a T-cell lymphoma. The small bowel usually shows ulceration, frequently with perforation, and a mass may or may not be present. The infiltrate shows a varying cytologic composition with an admixture of small, medium, and larger atypical lymphoid cells. Anaplastic cells strongly positive for CD30 can be present. The adjacent small bowel can show villous atrophy associated with celiac disease.⁶⁴ The neoplastic cells are CD3⁺, CD7⁺ T cells that also express the homing receptor CD103 (HML-1). The cells express cytotoxic molecules, a feature shared by nearly all extranodal T-cell lymphomas.

This disease occurs in adults, the majority of whom have either overt or clinically silent gluten-sensitive enteropathy. Patients usually present with abdominal symptoms such as pain, small-bowel perforation, and associated peritonitis. The clinical course is aggressive.

HEPATOSPLENIC T-CELL LYMPHOMA (HSTCL)

The majority of peripheral T lymphocytes belong to the $\alpha\beta$ T-cell receptor subset, whereas only a minority express the $\gamma\delta$ T-cell receptor. Similarly, most peripheral T-cell lymphomas are of $\alpha\beta$ T-cell derivation. However, there is a unique subtype of peripheral T-cell lymphoma that in most cases is derived from $\gamma\delta$ T cells.

HSTCL presents with marked hepatosplenomegaly.⁶⁵ The homing pattern manifested by the malignant cells is similar to that of normal $\gamma\delta$ T cells, which also populate the sinusoidal areas of the spleen.

HSTCL shows a marked male predominance and most patients are young adults.⁶⁶ The clinical presentation is that of marked hepatosplenomegaly in the absence of lymphadenopathy. Abnormal cells are usually present in the bone marrow but may be difficult to identify. They selectively infiltrate the bone marrow sinusoids and can be most easily recognized with immunohistochemical stains.

The cells of HSTCL are usually moderate in size, with a rim of pale cytoplasm. The nuclear chromatin is loosely condensed, with small inconspicuous nucleoli, and usually some irregularity of the nuclear contour can be seen. The liver and spleen show marked sinusoidal infiltration, with sparing of both portal triads and white pulp, respectively. The neoplastic cells have a phenotype that resembles that of normal $\gamma\delta$ T cells, usually expressing neither CD4 nor CD8. CD56 is often positive.^{65,66} *In situ* hybridization for EBV is negative.⁶⁶ Isochromosome 7 is a consistent cytogenetic abnormality, usually seen in conjunction with trisomy 8.⁶⁷

Rare cases with similar morphological and biological features are derived from $\alpha\beta$ T cells.

Clinically, HSTCL is aggressive.⁶⁶ Although patients may respond initially to chemotherapy, relapse occurs in the vast majority of cases and the median survival is less than 3 years. Other $\gamma\delta$ T-cell lymphomas exist, usually presenting in extranodal sites such as the skin and intestine but they are unrelated to HSTCL.

HODGKIN LYMPHOMA (HODGKIN DISEASE)

HD and non-Hodgkin lymphoma have long been regarded as distinct disease entities based on their differences in pathology, phenotype, clinical features, and response to therapy. In recent years evidence has been accumulating that the malignant cell of HD is in nearly all cases an altered B cell.^{68,69} Therefore, it is not surprising that both biological and clinical overlaps should occur between these two lymphoma groups, as also shown by gene expression profiling in PMBCL and classic Hodgkin cell lines.^{34,35} Although we have become aware of this closer relationship from the histogenetic point of view (hence the name Hodgkin lymphoma), these disorders are still treated with different modalities. The diagnosis of classic HL depends on the identification of Reed–Sternberg (RS) cells with an appropriate growth pattern (often interfollicular) in an inflammatory background composed of small T lymphocytes, plasma cells, histiocytes, and granulocytes (often eosinophils).

All cases of classic HL share certain immunophenotypic and genotypic features. The phenotype is CD30⁺, CD15^{+/−}, CD45[−], and EMA[−]. Expression of B-cell-associated antigens is seen in up to 75% of cases. However, when present, CD20 staining is weaker than the normal B cells and variable in intensity among individual tumor cells. CD79a is usually negative. Ig and T-cell receptor genes are usually germline, but rearrangements of Ig genes are reported in some cases, usually with faint

bands. More recently, using microdissection and single-cell polymerase chain reaction (PCR) amplification for Ig, several groups have shown clonal rearrangement of the Ig gene accompanied by frequent somatic mutations.^{68,69} EBV is associated with classic HL in 15–70% of cases, depending on the subtype.

Sufficient evidence has emerged in recent years to warrant the recognition of nodular lymphocyte-predominant HD as a distinct entity. Although it resembles other types of HL in having a minority of putative neoplastic cells on a background of benign inflammatory cells, it differs morphologically, immunophenotypically, and clinically from classic HD. The older term paraganuloma has been used by some as a synonym for this distinctive tumor.

The category of diffuse lymphocyte predominance in the Rye classification probably includes cases more closely related to classic HL (see section on classic Hodgkin lymphoma, lymphocyte-rich, below).

The WHO classification retains the basic division of HD into classic HD and nodular lymphocyte-predominant HD, which was already proposed by the REAL classification. The renamed Hodgkin lymphoma reflects the acknowledgment that this disease is indeed a lymphoma and not an atypical reactive process.

NODULAR LYMPHOCYTE-PREDOMINANT HODGKIN LYMPHOMA (NLPHL)

NLPHL usually has a nodular growth pattern, with or without diffuse areas; it is rarely purely diffuse. Nodularity may be more easily recognized using immunohistologic stains with anti-B-cell or anti-follicular dendritic cell (FDC) antibodies. Progressively transformed germinal centers are often seen in partially involved lymph nodes or other lymph node sites. The atypical cells have vesicular, polylobated nuclei and small nucleoli; these have been called lymphocytic and/or histiocytic (L&H) cells, or “popcorn” cells. Although these cells may be very numerous, usually no diagnostic RS cells are found. The background is predominantly lymphocytes with or without epithelioid histiocyte clusters. Plasma cells are infrequent, and eosinophils and neutrophils are rarely seen. Occasionally sclerosis may cause lesions to resemble nodular sclerosis.

The atypical cells are CD45⁺-expressing B-cell-associated antigens (CD19, 20, 22, 79a), CDw75⁺, EMA^{+/−} CD15[−], CD30^{+/+} and usually SIg[−] by routine techniques, although one study reported light-chain restriction. J chain has been demonstrated in many cases. Small lymphocytes in the nodules are predominantly B cells with a mantle-zone phenotype. However, numerous T cells are present, with CD57⁺ T cells surrounding the L&H cells. The proportion of T cells tends to increase over time in sequential biopsies.⁷⁰ A prominent meshwork of FDC is present within the nodules.⁷⁰ Ig and T-cell receptor genes are germline by Southern blot analysis. However, by single-cell PCR amplification for Ig it has been shown that the L&H cells are either polyclonal and/or clonal. Large cells are EBV-negative in most cases.

NLPHL occurs at all ages, in adults more commonly than in children, and in males more than in females. It usually involves peripheral lymph nodes, with sparing of the mediastinum. It is usually localized at diagnosis, but rarely may be disseminated. Survival is long, with or without treatment, for localized cases. Late relapses have been reported to be more common than in other types of HL; it may be associated with, or progress to, large B-cell lymphoma.⁷¹ Prospective clinical studies using

CLINICAL PEARLS

HODGKIN LYMPHOMA

- >> B-cell lineage established in nearly all cases.
- >> Reed–Sternberg cell, the hallmark of the disease, represents a “crippled” germinal-center B cell
- >> Nodular lymphocyte-predominant Hodgkin lymphoma considered a related but distinct entity
- >> Eighty percent of patients are curable with current therapy
- >> Stage of disease guides the choice of therapy; even patients with advanced-stage disease may be cured
- >> Late complications from treatment include acute leukemia (alkylating agents with extended-field radiation therapy), second solid tumors (radiation therapy), and premature atherosclerotic coronary artery disease (radiation therapy)
- >> Cause of death in the first 5–10 years is mainly Hodgkin lymphoma; after 10 years, mainly secondary malignant tumors

different forms of treatment should be attempted to determine the optimal approach to this disorder.

CLASSIC HODGKIN LYMPHOMA, NODULAR SCLEROSIS (NSHL)

This variant is most common in adolescents and young adults, but can occur at any age; female cases equal or exceed those in males. The mediastinum is commonly involved; stage and bulk of disease have prognostic importance. NSHL is often curable; however, in long-term survivors the risk of secondary malignancies is increased, especially in those receiving both radiation and chemotherapy.

The tumor has at least a partially nodular pattern, with fibrous bands separating the nodules in most cases. Diffuse areas may be present, as is necrosis. The characteristic cell is the lacunar-type RS cell, which may be very numerous. Diagnostic RS cells are usually also present. The background contains lymphocytes, histiocytes, plasma cells, eosinophils, and neutrophils. Subclassification according to the number of atypical cells may be clinically relevant; several grading schemes exist (NSI/II, syncytial variant, lymphocyte-depleted, cellular phase). However, clinical trials have shown conflicting results. For routine clinical purposes grading is not required according to the WHO clinical advisory report. However, grading may be useful for clinical trials. The grading scheme of the British National Lymphoma Investigation (BNLI) (NSI/II) is recommended. The immunophenotype and genotype are characteristic of classic HD.

CLASSIC HODGKIN LYMPHOMA, MIXED CELLULARITY (HLMC)

Patients are usually adults; males outnumber females and the stage may be more advanced than in nodular sclerosis or lymphoplasmacytic types, involving lymph nodes, spleen, liver, or marrow. The course is moderately aggressive but is often curable.

The infiltrate is diffuse, without band-forming sclerosis, although fine interstitial fibrosis may be present (Fig. 77.4). RS cells are of the classic type, although some lacunar cells may be seen. The inflammatory background is similar to that of other subtypes of classic HL and the immunophenotype and genotype are also similar. The diagnosis is made on routine sections, and immunophenotyping studies are at best an adjunct to the diagnosis.

CLASSIC HODGKIN LYMPHOMA, LYMPHOCYTE DEPLETION (HLLD)

This is the least common variant of HL and is most common in older people, in HIV-positive individuals, and in nonindustrialized countries. It frequently presents with abdominal lymphadenopathy, spleen, liver, and bone marrow involvement, without peripheral adenopathy. The stage is usually advanced at diagnosis; however, response to treatment is reported not to differ from other subtypes.

The infiltrate is diffuse and often appears hypocellular, owing to the presence of diffuse fibrosis and necrosis. Relative to the number of normal lymphocytes there are large numbers of RS cells and occasional bizarre 'sarcomatous' variants, with a paucity of other inflammatory cells. Confluent sheets of RS cells and variants may occur and rarely predominate ('reticular' variant, or 'Hodgkin sarcoma').

Fig. 77.4 Classic Hodgkin lymphoma, mixed cellularity subtype. A classic Reed-Sternberg cell is shown in a mixed inflammatory background with eosinophils, plasma cells, histiocytes, and small lymphocytes.

The immunophenotype is characteristic of classic HL. Since the histologic differential diagnosis often includes B- or T-large-cell lymphoma or ALCL, immunohistochemistry should be performed in most cases. EBV is positive in the majority of cases.

CLASSIC HODGKIN LYMPHOMA, LYMPHOCYTE-RICH (HLLR)

This type of classic HL may be nodular or diffuse and contains relatively infrequent RS cells, which are of the classic type, rather than the variants seen in NLPHL. Some lacunar cells may be present, in a background of lymphocytes, with infrequent eosinophils or plasma cells. In the past many cases of HLLR were misdiagnosed as nodular or diffuse lymphocyte-predominant HL. In contrast to NLPHL, the RS cells have the morphology and immunophenotype of classic RS cells. The immunophenotype and genetic features are similar to those of the other variants of classic HL. Patients usually present with localized disease.⁷¹ This variant of HL was a provisional form of HD in the REAL classification and has been retained in the WHO classification. The nodular form has been recognized more recently.⁷²

Monoclonal gammopathies

Robert A. Kyle, Angela Dispenzieri

78

The monoclonal gammopathies (paraproteinemias, dysproteinemias) are a group of disorders characterized by the proliferation of a single clone of plasma cells that produce an immunologically homogeneous (monoclonal) protein (M protein, paraprotein). Each M protein consists of two heavy polypeptide chains of the same class, designated as γ in IgG, α in IgA, μ in IgM, δ in IgD, and ϵ in IgE, and two associated light chains of the same type (κ or λ).

The monoclonal gammopathies include monoclonal gammopathy of undetermined significance (MGUS), multiple myeloma (MM), smoldering multiple myeloma (SMM), plasma cell leukemia, nonsecretory myeloma, solitary plasmacytoma (bone or extramedullary), POEMS (osteosclerotic myeloma), Waldenström's macroglobulinemia (WM), heavy-chain diseases (HCD), and primary systemic amyloidosis (AL).

The distribution of serum M proteins at Mayo Clinic from 1960 to 2005 is shown in Figure 78.1A and the diseases associated with them are shown in Figure 78.1B.

KEY CONCEPTS

CLASSIFICATION OF MONOCLONAL GAMMOPATHIES

- >> Monoclonal gammopathy of undetermined significance (MGUS) (benign monoclonal gammopathy)
- >> Multiple myeloma
- >> Multiple myeloma variants: smoldering multiple myeloma (SMM), plasma cell leukemia, nonsecretory myeloma, osteosclerotic myeloma (POEMS syndrome)
- >> Plasmacytoma: solitary plasmacytoma of bone, extramedullary plasmacytoma
- >> Waldenström's macroglobulinemia
- >> Heavy-chain diseases (α , γ , and μ)
- >> Primary amyloidosis (AL)

■ RECOGNITION OF M PROTEINS IN SERUM AND URINE ■

High-resolution agarose gel electrophoresis is preferred for the detection of an M protein. Immunofixation should be used to confirm the presence of an M protein and to identify the heavy-chain type and the light-chain class.¹ Serum protein electrophoresis should be performed whenever MM, WM, or AL is suspected, and if clinical suspicion is high, immunofixation studies should be done despite a normal serum electrophoretic pattern. These studies are also indicated in the presence of unexplained back pain, weakness or fatigue, recurrent infections, anemia, hypercalcemia, renal insufficiency, osteoporosis, or lytic lesions. It should also be performed in all patients with sensorimotor peripheral neuropathy, nephrotic syndrome, orthostatic hypotension, refractory congestive heart failure, carpal tunnel syndrome, or malabsorption of unknown cause because the presence of an M protein in one of these syndromes strongly suggests AL.

An M protein appears as a narrow peak or spike in the densitometer tracing or as a discrete band on agarose gel. In contrast, an excess of polyclonal immunoglobulins (having one or more heavy-chain types and both κ and λ light chains) produces a broad-based peak or band. It is important to differentiate an M protein from a polyclonal increase because the former is associated with a neoplastic process or a potentially malignant condition, whereas a polyclonal increase in immunoglobulins is associated with a reactive or inflammatory process. An M protein may exist even when the total protein level, beta (β)- and gamma (γ)-globulin concentrations, and quantitative immunoglobulin values are all within the normal limits. A monoclonal light chain in the serum (Bence Jones proteinemia) is rarely recognized with agarose gel electrophoresis. Immunofixation is recommended for identification of an M protein.

Rate nephelometry is the preferred method for quantitation of immunoglobulins because it is not affected by molecular size. The nephelometry value for immunoglobulin M (IgM), and occasionally IgG or IgA, is higher than that obtained with the densitometer tracing of serum protein electrophoresis. One must use either electrophoresis or nephelometric quantitation of immunoglobulins throughout the course of a patient's illness instead of alternating the techniques because of the differences in results.

Fig. 78.1 (A) Monoclonal gammopathies Mayo Clinic 1960–2005. **(B)** Monoclonal serum proteins Mayo Clinic 1960–2005.

Immunofixation is the preferred technique for identifying a monoclonal light chain in urine. A 24-hour urine specimen should be collected and the amount of M protein calculated on the base of the densitometer tracing and the 24-hour urine protein content. The amount of M protein is a direct reflection of the size of the tumor mass. The heat test for Bence Jones (monoclonal light-chain) proteinuria is unsatisfactory.

Measurement of free light-chain (FLC) has been introduced into clinical practice. This automated nephelometric assay measures the level of free κ and λ light chains in the serum. The normal ratio for FLC κ/λ is 0.26–1.65. In a series of 1020 patients at Mayo Clinic in whom an FLC assay was ordered, 88% had a monoclonal plasma cell disorder. The 121 patients who did not have a monoclonal protein had a normal FLC κ/λ ratio. Among 110 untreated patients with AL, the combination of serum–urine immunofixation and serum FLC detected an abnormal result in 99% of patients.²

MONOCLONAL GAMMOPATHY OF UNDETERMINED SIGNIFICANCE

MGUS is characterized by an M-protein concentration < 3 g/dl; fewer than 10% plasma cells in the bone marrow; no or only small amounts of M protein in the urine; absence of lytic bone lesions, anemia, hypercalcemia,

and renal insufficiency related to the plasma cell proliferative process. Although this disorder has been considered benign, it is known that symptomatic MM or related disorders can develop in many patients and for this reason the term MGUS is more appropriate.

MGUS has been reported in 3% of patients over 70 years and 1% of persons older than 50. In order to determine the prevalence, serum samples were obtained from 21 463 (77%) of the 28 038 enumerated residents of Olmsted County, Minnesota, who were 50 years of age or older.³ MGUS was identified in 694 (3.2%) of these persons. Age-adjusted rates were higher in men than in women (4% versus 2.7%, $P = 0.001$). The prevalence of MGUS was 5.3% among persons 70 years of age or older and 7.5% among those 85 years of age or older. In both sexes the prevalence increased with advancing age and was almost four times as high among persons 80 years of age or older than among those 50–59 years of age (Table 78.1). The isotype of the monoclonal protein was IgG in 69% of the 694 with MGUS, IgM in 17%, IgA in 11%, and biclonal in 3%. The concentration of immunoglobulins was less than 1.0 g/dl in 63.5% and at least 2.0 g/dl in only 4.5% of the 694 persons. The median value was 0.5 g/dl. The level of uninvolved (normal, polyclonal) immunoglobulins was reduced in 28% of the 447 patients in whom quantitative immunoglobulins were measured. Urine from 70 persons with MGUS showed a monoclonal kappa protein in 16.5% or lambda in 5%.³ The incidence of MGUS is higher in African Americans than in Caucasians.⁴

Because of its frequency, it is of great importance to know whether the M protein will remain stable or will progress to MM, WM, AL, or other related disorders. At Mayo Clinic, 241 patients with an apparently benign monoclonal gammopathy have been followed for 3579 person-years (median, 13.7 years; range 0–39 years).⁵ The bone marrow contained 1–10% plasma cells (median, 3%).

The actuarial risk of malignant transformation was 17% at 10 years, 34% at 20 years, and 39% at 25 years. The interval from recognition of M protein to the diagnosis of serious disease ranged from 1 to 32 years (median, 10.4 years). In 10 patients, MM was diagnosed more than 20 years after detection of the M protein. The mode of development of MM was variable, in that some patients remained stable for many years and MM developed gradually or suddenly, whereas in others there was a steady increase in the M-protein level until they became symptomatic. The median duration of survival after the diagnosis of MM was 33 months, which is not different from those who develop myeloma *de novo*.

In order to confirm the findings of the 241 Mayo Clinic patients from the USA and other countries, which may be subject to referral bias, we conducted a population-based study of a group of 1384 patients with MGUS from the 11 counties of southeastern Minnesota evaluated at the Mayo Clinic from 1960 to 1994.⁶ The median age at diagnosis of MGUS was 72 years compared to 64 years in the 241-patient cohort. Fifty-four percent of patients were men and only 2% were < 40 years of age at diagnosis.⁶ The size of the M protein at diagnosis ranged from unmeasurable to 3.0 g/dl (median 1.3 g/dl). The M protein was IgG in 70%, IgM in 15%, IgA in 12%, and biclonal in 3%. The uninvolved (normal or background) immunoglobulins were reduced in 38% of 840 patients who were evaluated. Of the 418 patients who had immunofixation of urine, 31% had a monoclonal light chain. In each case anemia or renal insufficiency, when present, was not attributable to the monoclonal plasma cell process.

The 1384 patients were followed for a total of 11 009 person-years (median, 15.4 years; range, 0–35 years), during which time 963 (70%) died. During follow-up, MM, AL, WM, chronic lymphocytic leukemia, or plasmacytoma developed in 115 patients (8%) (Table 78.2). The

Table 78.1 Prevalence of monoclonal gammopathy of undetermined significance (MGUS) according to age group and sex among residents of Olmsted County, Minnesota

Age (years)	Women	Men	Total
Number/total number (percent)^a			
50–59	59/4335 (1.4)	82/4038 (2.0)	141/8373 (1.7)
60–69	73/3155 (2.3)	105/2864 (3.7)	178/6019 (3.0)
70–79	101/2650 (3.8)	104/1858 (5.6)	205/4508 (4.6)
≥ 80	111/1854 (6.0)	59/709 (8.3)	170/2563 (6.6)
Total	344/11,994 (2.9) ^b	350/9469 (3.7) ^b	694/21463 (3.2) ^{b, c}

From Kyle RA, Therneau TM, Rajkumar SV, et al. Prevalence of monoclonal gammopathy of undetermined significance. *N Engl J Med* 2006; 354: 1362–1369, with permission from the Massachusetts Medical Society.

^aThe percentage was calculated as the number of patients with MGUS divided by the number who were tested.

^bPrevalence was age-adjusted to the 2000 US population as follows: men, 4.0% (95% confidence interval, 3.5–4.4); women, 2.7% (95% confidence interval, 2.4–3.0) and total, 3.2% (95% confidence interval, 3.0–3.5).

^cPrevalence was age- and sex-adjusted to the 2000 US total population.

Table 78.2 Risk of progression among 1384 residents of southeastern Minnesota in whom monoclonal gammopathy of undetermined significance was diagnosed in 1960 through 1994^a

Type of progression	Observed	Expected	Relative risk (95% CI)
	No. of patients	No. of patients	
Multiple myeloma	75	3.0	25.0 (20–32)
Lymphoma	19 ^b	7.8	2.4 (2–4)
Primary amyloidosis	10	1.2	8.4 (4–16)
Macroglobulinemia	7	0.2	46.0 (19–95)
Chronic lymphocytic leukemia	3 ^c	3.5	0.9 (0.2–3)
Plasmacytoma	1	0.1	8.5 (0.2–47)
Total	115	15.8	7.3 (6–9)

CI, confidence interval.

^aExpected numbers of cases were derived from the age- and sex-matched white population of the Surveillance, Epidemiology, and End Results program in Iowa,⁷ except for primary amyloidosis, for which data are from Kyle et al.⁸

^bAll 19 patients had serum immunoglobulin M (IgM) monoclonal protein. If the 30 patients with IgM, IgA, or IgG monoclonal protein and lymphoma were included, the relative risk would be 3–9 (95% confidence interval, 2.6–5.5).

^cAll 3 patients had serum IgM monoclonal protein. If all 6 patients with IgM, IgA, or IgG monoclonal protein and chronic lymphocytic leukemia were included, the relative risk would be 1.7 (95% confidence interval, 0.6–3.7).

From Kyle RA, Therneau TM, Rajkumar SV, et al. A long-term study of prognosis in monoclonal gammopathy of undetermined significance [see comment]. *N Engl J Med* 2002; 346: 564–569, with permission from the Massachusetts Medical Society.

cumulative probability of progression to one of these disorders was 10% at 10 years, 21% at 20 years, and 26% at 25 years (Fig. 78.2). The overall risk of progression was about 1% per year but it must be emphasized that patients were at risk for progression even after 25 years or more of stable MGUS. In addition, there were 32 patients in whom the monoclonal protein value increased to more than 3 g/dl or the percentage of plasma cells increased to more than 10% but in whom symptomatic MM did not develop. At 20 years, the risk of death for patients with MGUS was 10% from plasma cell disorders and 72% from non-plasma cell disorders.

The number of patients with progression to a plasma cell neoplasm or a related disorder (115 patients) was more than seven times expected on the basis of incidence rates for those conditions in the general population (Table 78.2). The risk of developing MM, WM, or AL was increased 25-fold, 46-fold, and 8.4-fold respectively.

MM was diagnosed more than 10 years after the detection of the monoclonal protein in 24 (32%) of the 75 patients, and after 20 years of follow-up in 5 (7%) patients. Characteristics of these 75 patients were comparable with those of the 1027 patients with newly diagnosed MM

CLINICAL PEARLS

MONOCLONAL GAMMOPATHIES

- >> Monoclonal gammopathy of undetermined significance (MGUS) (benign monoclonal gammopathy) occurs in nearly 60% of all patients with a monoclonal gammopathy
- >> MGUS occurred in 3.2% of persons older than 50 years and in 5.3% of those older than 70 years in a population-based study of 21 463 residents of Olmsted County, Minnesota
- >> The risk of MGUS developing multiple myeloma, primary systemic amyloidosis, macroglobulinemia, or related disorders is 1% per year during long-term follow-up

who were referred to the Mayo Clinic from 1985 to 1998, except that the southeastern Minnesota patient population was older (median 72 versus 66 years) and had a smaller percentage of men (46% versus 60%).⁹

Similar findings have been reported in other series: the actuarial risk was 8.5% and 19.2% at 5 and 10 years respectively in one series of 128 patients with MGUS. In a report of 335 patients with MGUS, the frequency of progression after a median follow-up of 70 months was 6.8%.

PROGRESSION OF MGUS

The sequence of events responsible for progression of MGUS to myeloma or a related disorder is poorly understood. This has recently been reviewed.¹⁰ Almost one-half of patients with MGUS have immunoglobulin heavy-chain translocations consisting of t(11;14), t(4;14), and t(14;16). These translocations lead to dysregulation of putative oncogenes. Deletions of chromosome 13 have also been found in MGUS.

Risk factors for progression consist of size of the M-protein at diagnosis, type of M protein, presence of abnormal serum FLC ratio, and bone marrow plasma cell involvement. In a series of 1384 patients with MGUS from southeastern Minnesota, the size of the M-protein at diagnosis was the most important predictor of progression. The risk of progression to MM or a related disorder 20 years after the diagnosis of MGUS was 14% for patients with an initial M protein value of 0.5 g/dl and 49% for those presenting with an M spike of 2.5 g/dl (Fig. 78.2). The risk of progression of a serum M protein of 1.5 g/dl was almost twice the risk of progression with a value of 0.5 g/dl and the risk of progression with 2.5 g/dl was 4.6 times that of a value of 0.5 g/dl. Patients with IgM or IgA protein had an increased risk of progression compared with those with IgG monoclonal protein ($P=0.001$).

An abnormal FLC ratio was detected in 379 (33%) of 1148 patients from the 1384 patients with MGUS from southeastern Minnesota. The risk of progression with an abnormal FLC ratio was significantly higher than that in patients with a normal ratio (hazard ratio 3.5; $P<0.001$) and was independent of the size and type of serum M protein. A new stratification model for determining the risk of progression of MGUS was developed in that study.¹¹ The number of plasma cells in the bone marrow may help predict progression.¹²

In our experience, age; gender; levels of hemoglobin, serum creatinine, and serum albumin; presence, type, and amount of monoclonal urinary light-chain; and reduction of uninvolved immunoglobulins have not helped to determine the risk of progression.

Fig. 78.2 Actuarial risk of full progression by serum monoclonal protein (M protein) value at diagnosis of monoclonal gammopathy of undetermined significance (MGUS) in persons from southeastern Minnesota. (From Kyle et al. Immunological Reviews, 2003; 194: 112–139, with permission of Blackwell Publishing.)

MANAGEMENT OF MGUS

Despite the results of sophisticated laboratory tests, MM is differentiated from MGUS on the basis of clinical factors such as symptoms, anemia, hypercalcemia, renal insufficiency, and lytic bone lesions. The serum and urine M proteins must be measured periodically and a clinical evaluation conducted to determine whether MM, AL, WM, or a lymphoproliferative disorder has developed.

If a patient has no features of MM or AL, the serum protein value (IgG type) is less than 1.5 g/dl and FLC ratio is normal, the serum protein electrophoresis should be repeated in 6–12 months and, if the results are stable, annually.

If the patient has an M-protein value of > 1.5 g/dl, a 24-hour urine specimen should be collected for electrophoresis and immunofixation. A meta-static bone survey and bone marrow aspiration and biopsy should also be done. Determination of the plasma cell labeling index (PCLI), search for circulating plasma cells in the blood, and cytogenetic studies should be performed if available. Levels of β_2 -microglobulin and C-reactive protein should also be determined. Serum protein electrophoresis should be performed in 3–6 months and if the results are stable it should be repeated in 6 months and then annually or sooner if symptoms develop. Patients should be instructed to contact their physician if there is any change in clinical condition.

ASSOCIATION OF MONOCLONAL GAMMOPATHIES WITH OTHER DISEASES

Although MGUS frequently exists without any other abnormalities, certain diseases are associated with it, as would be expected in an older population. There may be an apparent association because of differences in the referral practices or in other selected patient groups. Appropriate control populations are essential for determining whether the association is merely a coincidence.

M proteins have been noted in lymphoproliferative disorders, leukemia, other hematologic diseases, connective tissue disorders, and neurologic conditions such as peripheral neuropathy. Dermatologic diseases, including lichen myxedematosus, pyoderma gangrenosum, necrobiotic

xanthogranuloma, and plane xanthomatosis, have been associated with an M protein. M proteins have also been found after renal, bone marrow, or liver transplantation as a result of immunosuppressive therapy. More detailed reviews of the association of monoclonal gammopathy with nonplasma cell disorders have been published.¹⁰

VARIANTS OF MGUS

IgM MGUS

IgM MGUS comprises 20% of all patients with MGUS. IgM MGUS was diagnosed in 213 Mayo Clinic patients who resided in the 11 counties of southeastern Minnesota.¹³ Non-Hodgkin's lymphoma ($n=17$), WM ($n=6$), chronic lymphocytic leukemia ($n=3$), or AL ($n=3$) developed in 29 (14%) of the 213 IgM patients with a relative risk of 15, 262, 6, and 16 respectively. The risk of progression was 14%, 26%, 34%, and 41% for concentrations of ≤ 0.5 , 1.5, 2.0, and ≥ 2.5 g/dl respectively. Progression occurred at a rate of approximately 1.5%/year.

Biclonal gammopathies

Biclonal gammopathies occur in approximately 4–6% of patients with monoclonal gammopathies and have similar clinical features. Two-thirds of cases of biclonal gammopathy are of undetermined significance.¹⁴ The remainder have MM, AL, WM, or other lymphoproliferative disorders. More than 25 cases of triclonal gammopathy have been reported.

Idiopathic Bence Jones proteinuria

In most patients, the presence of Bence Jones proteinuria indicates MM, AL, WM, or other lymphoproliferative disorders. However, it may follow a benign course for many years. Patients with 'idiopathic' Bence Jones proteinuria must be observed indefinitely, because MM or AL will eventually develop in most of those with > 1 g of Bence Jones proteinuria/24 hours.¹⁵

MULTIPLE MYELOMA

MM (myelomatosis, Kahler's disease) is characterized by the neoplastic proliferation of a single clone of plasma cells producing an M protein. This proliferation often results in skeletal destruction, with osteolytic lesions or pathologic fractures producing pain, hypercalcemia, and anemia. An excess of M protein can contribute to renal failure, the hyperviscosity syndrome, or recurrent bacterial infections.

EPIDEMIOLOGY

The annual incidence of MM is 4.3 per 100 000.¹⁶ The apparent increased incidence during the past few decades is probably related more to the increased availability and use of medical facilities in the elderly and to improved diagnostic techniques rather than an actual increased incidence. MM represents 1% of all malignant disease and slightly more than 10% of hematologic malignancies. Its incidence in African Americans is twice that in Caucasians, and it is slightly more frequent in men than in women. MM occurs in all races and all geographic regions, but rates are lower in Asian populations. Only 10% are younger than 50 years and 2% are younger than 40 years. The median age is 66 years.⁹

BIOLOGIC ASPECTS

Plasma cells are cytoplasm Ig (cIg⁺) and express surface CD38. A small subset of myeloma cells express CD10 and 15–20% express CD20. CD56 (N-CAM) is expressed on the majority of malignant plasma cells, but CD34 is not. The clonogenic cell in MM has not been demonstrated with certainty. There is evidence that plasma cell precursors of myeloma circulate in the peripheral blood. The current hypothesis is that, by means of adhesion molecules, circulating clonogenic myeloma cells home to the bone marrow, where they find an appropriate microenvironment to differentiate and expand further.

Approximately 50% of patients have translocations that involve the immunoglobulin heavy-chain locus on chromosome 14q32 and 1 of 5 partner chromosomes: 11q13(CCND-1), the most common, 4p16.3(FGFR-3 and MMSET), 6p21(CDND-3), 16q23(C-mAF), and 20q11 (mAF- β).¹⁷ Other cytogenetic changes include M-RAS, K-RAS, and P16 methylation.

Conventional cytogenetic studies show abnormal karyotypes in only 30–40% of patients. Newer techniques using interphase fluorescence *in-situ* hybridization (FISH) have detected a higher frequency of abnormalities.

CLINICAL MANIFESTATIONS

Bone pain, usually in the back or chest, is present at the time of diagnosis in about 60% of patients and is usually aggravated by movement.⁹ Weakness and fatigue are common and usually associated with anemia. The major symptoms may result from an acute infection, renal failure, hypercalcemia, or amyloidosis. Pallor is the most frequent physical finding.

RENAL INVOLVEMENT

The serum creatinine level is 2 mg/dl or more in one-fifth of patients at diagnosis. Two major causes of renal failure are "myeloma kidney" and hypercalcemia. Myeloma kidney is characterized by the presence of large, dense, waxy, laminated casts in the distal and collecting tubules. Hypercalcemia, which is present in 15% of patients initially, is a major and treatable cause of renal insufficiency. Dehydration, infections, or nonsteroidal antiinflammatory agents may all contribute to renal failure.

SKELETAL INVOLVEMENT

Almost 80% of patients have lytic lesions, osteoporosis, or fractures with conventional radiographs at diagnosis. Magnetic resonance imaging (MRI) or computed tomography (CT) is most helpful in the detection of extramedullary plasmacytomas compressing the spinal cord in patients with severe back pain but no abnormalities on routine radiographs.

NEUROLOGIC INVOLVEMENT

Radiculopathy from nerve compression by an extradural plasmacytoma or by the collapsed bone itself is the most frequent neurologic complication. Compression of the spinal cord occurs in about 5% of patients and must be recognized and treated without delay. Peripheral neuropathy is rare in MM, and, when present, is usually due to amyloidosis. Leptomeningeal myelomatosis is uncommon but is being recognized more frequently. Intracranial plasmacytomas are rare.

Table 78.3 Laboratory tests in 1027 patients with multiple myeloma

	<i>n</i>	Median	Range	Distribution of Results	% of Patients
Hemoglobin (g/dl)	1025	10.9	2.7–17.2	≤ 8 8.1–10.0 10.1–12 > 12	7 28 37 28
Creatinine (mg/dl)	1020	1.2	0.5–18.2	< 1.3 1.3–1.9 ≥ 2	52 29 19
Calcium (mg/dl)	1018	9.6	7.0–17.2	≤ 10.1 10.2–10.9 ≥ 11	72 15 13

β ₂ -microglobulin	735	3.9	0.8–82	≤ 2.7 2.8–4.0 4.1–6.0 > 6	25 28 21 26
C-reactive protein	285	0.4	0.01–49	< 0.8 > 5.0	66 10

From Kyle RA, Gertz MA, Witzig TE, et al. Review of 1027 patients with newly diagnosed multiple myeloma [see comment]. Mayo Clin Proc 2003; 78: 21–33, with permission from the Mayo Clinic.

OTHER SYSTEMIC INVOLVEMENT

The incidence of infections is increased in MM. Impairment of antibody response, reduction of normal immunoglobulins, neutropenia, and treatment with glucocorticoids all contribute to infection. Hepatomegaly from plasma cell infiltration is rare. Plasmacytomas of the ribs are often present. Diffuse pulmonary involvement and pleural effusion from plasma cell infiltration are rare and usually occur late in the course of the disease.

LABORATORY FINDINGS

In a series of 1027 myeloma patients, approximately three-fourths had a normocytic, normochromic anemia at diagnosis⁹ (Table 78.3). Hypercalcemia (≥ 11 mg/dl) occurred in 13% and 19% had an increase in the serum creatinine to ≥ 2.0 mg/dL. The serum protein electrophoretic pattern showed a spike or localized band in over 80% of patients at diagnosis. An M protein is found in the serum in 93% of patients, of which about half had an IgG M protein and approximately a fifth had IgA, and more than 15% had a free monoclonal light chain (Bence Jones proteinemia). Immunofixation of the urine revealed an M protein in 78% of patients. An M protein is found in the serum or urine in 97% of patients with MM at the time of diagnosis and the relative frequency of κ:λ is 2:1. Plasma cells usually constitute more than 10% of all nucleated cells in the bone marrow, but the number may range from less than 5% to almost 100%.

CLINICAL PEARLS

MULTIPLE MYELOMA

At the time of diagnosis 97% of patients have a monoclonal protein in the serum or urine

The most important prognostic factors are cytogenetic changes, plasma cell labeling index, and β₂-microglobulin level

DIFFERENTIAL DIAGNOSIS

The diagnosis of MM depends on the presence of an increased number of plasma cells in the bone marrow (usually > 10%), and an M protein in the serum (usually > 3 g/dl), or a monoclonal light chain in the urine, or osteolytic lesions. Clinical features of MM must also be present. Metastatic carcinoma, connective tissue disorders, and lymphoma must be considered in the differential diagnosis.

The concentration of the serum M protein, the amount of urine M protein, the number of bone marrow plasma cells, the hemoglobin, calcium, and creatinine levels and presence of lytic lesions are all helpful in differentiating MGUS and SMM from MM. The level of uninvolved serum immunoglobulins is not helpful because in one-third of the patients with MGUS they are reduced. The PCLI, which measures the synthesis of DNA, is helpful in differentiating MGUS or SMM from

MM. Monoclonal plasma cells can be detected in the peripheral blood of 80% of patients with active MM. In contrast, patients with MGUS or SMM have few or no circulating plasma cells.

Differentiation of AL and MM is arbitrary because both diseases are plasma cell-proliferative disorders with different manifestations. In AL, the proportion of bone marrow plasma cells is usually less than 20%, there are no osteolytic lesions, and the amount of Bence Jones proteinuria is modest.

No single test reliably differentiates a patient with MGUS from one in whom MM or other malignant disease will subsequently develop. The most reliable means of differentiation is serial measurement of the M-protein value in the serum and urine and periodic evaluation of the pertinent clinical and laboratory features.

PROGNOSTIC FACTORS

The median duration of survival in MM is approximately 3 years, but there is a great deal of variability between patients. Approximately 25% survive 5 or more years, but fewer than 5% live longer than 10 years. There is no difference in survival of light-chain or heavy-chain myeloma (Fig. 78.3).

The Durie-Salmon clinical staging system is based on a combination of factors that correlate with the myeloma cell mass. However, the unreliability of this system and its many shortcomings led to the search for other prognostic factors. The new International Staging System, a collaborative effort by investigators from 17 institutions worldwide and data on 11 171 patients divides patients into three stages on the basis of β_2 -microglobulin and albumin levels at diagnosis.¹⁸ The bone marrow PCL, cytogenetics, and β_2 -microglobulin levels are the most important prognostic factors in previously untreated patients.

TREATMENT

Most patients with MM have symptomatic disease at diagnosis and require chemotherapy. However, not all patients who fulfill the minimal criteria for the diagnosis of MM should be treated, and patients with SMM or MGUS should be observed until progression occurs. An

increasing level of the M protein in the serum or urine, development of anemia, hypercalcemia, renal insufficiency, or the occurrence of lytic bone lesions or extramedullary plasmacytomas are all indications for therapy. If there is doubt about whether to begin the therapy, the most reasonable approach is to re-evaluate the patient in 2 months and delay treatment until progressive disease is evident. There is no evidence that early treatment of MM is advantageous. Therapy of MM has been reviewed.^{19, 20}

Autologous stem cell transplant

If patients with newly diagnosed MM are considered eligible for autologous stem cell transplant (ASCT) it is important to avoid alkylating agents such as melphalan which can damage stem cells and interfere with adequate hematopoietic stem cell collection. Some patients older than 70 years are physiologically younger and can undergo a transplant, whereas some patients younger than age 70 years may have medical problems and are not suitable candidates for ASCT. Dexamethasone alone or thalidomide plus dexamethasone are two of the most commonly used induction regimens for patients who are candidates for ASCT. A randomized trial comparing dexamethasone 40 mg orally on days 1–4, 9–12, and 17–20 repeated every 4 weeks or thalidomide 200 mg orally each day plus dexamethasone in the same dosage revealed a superior response rate for thalidomide plus dexamethasone (63% versus 41%) but a higher incidence of deep venous thrombosis.²¹ Patients should be anti-coagulated with low-molecular-weight heparin or warfarin in therapeutic doses. Aspirin may reduce the risk of thromboembolic complications and is an alternative. The intravenous regimen of VAD (vincristine, doxorubicin [Adriamycin], and dexamethasone) is infrequently used as induction therapy because of the increased risk of catheter-related sepsis and thrombosis. In a matched case-control study of 200 patients, the response rates with VAD were significantly inferior to those with thal-dex (76% versus 52%) respectively.²² Bortezomib (PS-341, Velcade) and lenalidomide (CC-5013, Revlimid) are currently being tested in clinical trials as initial therapy. Two large phase III trials are ongoing with lenalidomide/dexamethasone for induction therapy and it is likely that this oral regimen will prove to be a safer and more effective alternative to thalidomide and dexamethasone as initial therapy.

After stem cell collection, ASCT can proceed as soon as the patient has recovered or the transplant may be delayed and the patient treated with standard alkylating agent therapy, with the transplant being reserved for relapsed disease.

Melphalan (Alkeran) 200 mg/m² is the most widely used preparative regimen for ASCT. In two studies from France and the UK,²³ ASCT was superior to combination chemotherapy. Progression-free survival was longer, and the median overall survival was increased by approximately 1 year in the transplant group. Approximately 60% of our patients receiving ASCT are treated as outpatients, and the mortality is 1–2%. The role of intensive therapy has recently been reviewed.²⁴

With tandem (double) ASCT, patients receive a second planned ASCT after recovery from the first transplant. The benefit of a second ASCT is limited to patients in whom complete response or very good partial response (> 90% reduction in M-protein level) was not achieved with the first procedure.²⁵

Patients not eligible for ASCT

Patients who are not candidates for transplantation on the basis of age, performance status, and comorbidity are treated with alkylating agent therapy. Melphalan and prednisone, given orally, produce an objective

Fig. 78.3 Duration of survival in patients with light-chain myeloma and those with heavy-chain myeloma after diagnosis of multiple myeloma (MM). (From Kyle et al. Review of 1027 patients with newly diagnosed multiple myeloma. Mayo Clinic Proceedings, 2003; 78: 21–33), with permission from the Mayo Clinic.

THERAPEUTIC PRINCIPLES

TREATMENT OF MULTIPLE MYELOMA

- >> Consider an autologous peripheral blood stem-cell transplant in newly diagnosed patients
- >> Autologous peripheral blood stem-cell transplantation is not curative
- >> Oral melphalan and prednisone for patients ineligible for a peripheral stem cell transplant. The addition of thalidomide is promising
- >> Combinations of alkylating agents produce a higher response rate without improved survival compared to melphalan and prednisone
- >> Allogenic bone marrow transplant has a significant early mortality and is not recommended
- >> Novel agents for multiple myeloma include thalidomide, bortezomib, and lenalidomide

response in 50–60% of patients. Leukocyte and platelet counts should be determined at 3-week intervals after beginning therapy, because the melphalan dosage must be altered until midcycle neutropenia or thrombocytopenia occurs. Chemotherapy should be continued for at least 1 year or until the patient is in a plateau state with stable serum and urine M-protein levels and no progression of disease. Patients should be followed closely during the plateau state and the same chemotherapy should be reinstituted if relapse occurs after 6 months.

Because of the obvious shortcomings of melphalan and prednisone, various combinations of therapeutic agents have been used. In an overview of individual data of 4930 persons from 20 randomized trials comparing melphalan and prednisone with various combinations of therapeutic agents, response rates were significantly higher with combination chemotherapy (60%) than melphalan/prednisone (53%) ($P < 0.00001$). However, there was no significant difference in response duration or overall survival.²⁶

Two recent randomized trials have compared melphalan and prednisone to melphalan and prednisone plus thalidomide (MPT).^{27, 28} These trials show superior response rates and event-free survival with the latter regimen. Consequently, MPT is an additional standard option for patients with newly diagnosed myeloma who are not candidates for transplantation. MPT is associated with significant greater toxicity, including thrombosis; therefore, care must be exercised in patient selection as well as during therapy.²⁷

Maintenance Therapy

Maintenance therapy with interferon- α_2 is of limited value and is seldom used. Recent results from a large intergroup study showed no benefit with interferon as maintenance therapy.²⁹ Prednisone 50 mg q.o.d. may be useful for maintenance therapy. In a randomized study of 50 mg versus 10 mg of prednisone taken every 48 hours, the progression-free survival (14 versus 5 months) and overall survival (37 versus 26 months) were

significantly longer in the 50-mg regimen.³⁰ Preliminary results from a French randomized trial showed improvement in event-free overall survival with maintenance thalidomide plus pamidronate.³¹

Allogeneic bone marrow transplantation

Bone marrow transplantation from an identical-twin donor (syngeneic) is the treatment of choice if a donor is available. Results are superior to allogeneic transplantation.

Allogeneic bone marrow transplantation is advantageous because the graft contains no tumor cells and there may be a graft-versus-tumor effect. However, there is a mortality rate of at least 25%. Furthermore, 90–95% of patients with MM are ineligible because of their age, lack of a human leukocyte antigen (HLA)-matched sibling donor, or inadequate renal, pulmonary, or cardiac function. Currently, conventional allogeneic transplantation is associated with too-high a mortality and cannot be recommended. However, efforts are under way to reduce allogeneic transplant-related mortality using T-cell depletion or nonmyeloablative regimens. Nonmyeloablative (mini-allo) allogeneic protocols following ASCT are being pursued. The mortality is 10–15% and graft-versus-host disease occurs in about one-half of patients. Efforts are being made to reduce the toxicity of this approach. Currently, nonmyeloablative approaches should be limited to protocol studies.

REFRACTORY MULTIPLE MYELOMA

Cure rarely occurs, so that almost all patients who respond to chemotherapy or transplantation will eventually have a relapse if they do not die of another disease. Furthermore, at least one-third of patients treated initially do not obtain an objective response. Patients who are initially refractory or who become refractory to alkylating agent therapy generally have a low response to subsequent chemotherapy and a short survival. Until recently the highest response rates in such patients had been with VAD given intravenously for 96 hours or as a bolus injection. Many physicians choose single-agent dexamethasone instead because it accounts for 80% of the effect of VAD.

In the past decade, novel agents for the treatment of MM include thalidomide and its analogue, lenalidomide, and the proteasome inhibitor, bortezomib. Thalidomide is usually given in a dosage of 50–200 mg/daily. Objective responses occur in approximately one-third of patients with a median duration of response of approximately 12 months. The addition of dexamethasone increases the response rate. Side effects from thalidomide include weakness, fatigue, constipation, and somnolence. Thrombotic events, sensory motor peripheral neuropathy, and skin rashes are more troublesome side effects. Lenalidomide, an immunomodulatory derivative, has shown activity in previously treated patients. Phase II studies produce response in 30% of patients and constipation, somnolence, and neuropathy have not been troublesome. The lenalidomide dosage for myeloma is 25 mg orally on days 1–21 every 28 days. Higher response rates are seen when used in combination with dexamethasone. Bortezomib produced objective response in 35% of patients with relapsed, refractory myeloma who had received at least two prior therapeutic regimens. The median duration of response is approximately 12 months. Fatigue, anorexia, nausea and vomiting, fever, diarrhea, constipation, anemia, asthenia, peripheral neuropathy, neutropenia, and thrombocytopenia are adverse side effects.³²

■ TREATMENT OF COMPLICATIONS OF MULTIPLE MYELOMA ■

LOCAL THERAPY

Palliative radiation in a dosage of 20–30 Gy should be limited to patients with disabling pain who have a well-defined focal process that has not responded to chemotherapy or in the case of symptomatic spinal cord compression. Analgesics in combination with chemotherapy can usually control the pain. This approach is preferred to local radiation because pain frequently occurs in another site and local radiation does not benefit the patient with systemic disease.

HYPERCALCEMIA

Hypercalcemia (7 mg/dl) is present in almost 15% of patients at diagnosis. It should be suspected in the presence of anorexia, nausea, vomiting, polyuria, polydipsia, constipation, confusion, or stupor. Hypercalcemia also contributes to the development of renal insufficiency. Hydration and prednisone, 25 mg q.i.d., are effective in most cases. If not, a bisphosphonate such as zoledronic acid or pamidronate should be given. Patients with MM should be encouraged to be as active as possible because prolonged bedrest contributes to osteopenia and hypercalcemia.

SKELETAL LESIONS

Complications related to lytic skeletal lesions are common in MM. Patients should be encouraged to be as active as possible but to avoid trauma. Fixation of fractures or impending fractures of long bones with an intramedullary rod and methylmethacrylate has produced good results.

In a prospective placebo-controlled study, pamidronate showed a significant reduction in skeletal events (pathologic fractures, need for radiation or surgery to treat or prevent pathologic fractures, or spinal cord compression associated with compression fractures).²⁸

Intravenous bisphosphonates should be given to all patients who have lytic lesions, pathologic fractures, or severe osteopenia. Zoledronic acid (Zometa) 4 mg intravenously over 15–30 minutes every 4 weeks and pamidronate (Aredia) 90 mg intravenously over 2–3 hours every 4 weeks are equally efficacious. The dosage of bisphosphonates should be reduced in renal insufficiency. Because renal insufficiency or nephrotic-range proteinuria may occur, serum creatinine and 24-hour urine protein monitoring are necessary. One may consider reducing the intravenous bisphosphonate to every 3 months after 2 years unless there is evidence of progressive skeletal disease. Osteonecrosis of the jaw has been reported in patients receiving bisphosphonates. Although the relationship is unclear, it is essential to obtain a complete dental evaluation and perform preventive dental treatment prior to beginning bisphosphonates. Good oral hygiene should be practiced during therapy. Dental extractions or other invasive procedures should be avoided during bisphosphonate therapy. Management of osteonecrosis of the jaw should be conservative. Clodronate and ibandronate are alternatives and can be given orally.

Both vertebroplasty (injection of methylmethacrylate into a collapsed vertebral body) and kyphoplasty (introduction of an inflatable bone tamp into the vertebral body and, after inflation, the injection of methylmethacrylate into the cavity) have been used successfully to decrease pain and help restore height. Pain relief is generally rapid and can be long-lasting.

RENAL INSUFFICIENCY

Patients should be treated with dexamethasone alone or thalidomide plus dexamethasone or VAD to reduce the tumor mass as quickly as possible in patients with acute or subacute renal failure. A trial of plasmapheresis is reasonable in an attempt to prevent chronic dialysis but this has not been proven. Hemodialysis and peritoneal dialysis are equally effective and are necessary for patients with symptomatic azotemia. Renal transplantation for myeloma kidney may also be helpful. Maintenance of a high (3 l/day) urine output is important for preventing renal failure in patients with Bence Jones proteinuria.

ANEMIA

Anemia occurs in almost all patients during the course of MM. Symptomatic anemia during the plateau phase is benefited by the administration of erythropoietin in at least one-half of patients. Those with low serum erythropoietin values are more likely to respond, but most physicians proceed with a trial of erythropoietin, 150 U/kg three times weekly, or 40 000 U once a week. Darbepoetin (Aranesp), a long-lasting erythropoietin, may be given weekly or biweekly. There are no side effects and the major disadvantage is its cost. Red-cell transfusions may also be needed for anemia.

INFECTIONS

Prompt and appropriate therapy for bacterial infection is essential. Pneumococcal and influenza vaccines should be given to all patients despite their suboptimal antibody response. Intravenous immunoglobulin may be helpful for patients with recurrent infections but is very expensive.

SPINAL CORD COMPRESSION

Spinal cord compression should be suspected in patients with back pain, weakness, or paresthesias of the lower extremities, or bowel dysfunction. MRI or CT must be done immediately. Radiation therapy and dexamethasone are usually helpful and surgical compression is rarely necessary.

EMOTIONAL SUPPORT

All patients with MM need substantial and continuing emotional support. Quality-of-life issues must be in the forefront. The physician's approach must be positive in emphasizing the potential benefits of therapy. It is reassuring for patients to know that some survive for 10 years or more. It is vital that the physician caring for patients with MM has the interest and capacity for dealing with incurable disease over the span of years with assurance, sympathy, and resourcefulness.

VARIANTS OF MULTIPLE MYELOMA

SMOLDERING MULTIPLE MYELOMA

SMM is characterized by the presence of an M protein > 3 g/dl and/or more than 10% plasma cells in the bone marrow but no evidence of anemia, hypercalcemia, skeletal lesions, or renal insufficiency.³³ SMM accounts for 10–15% of all cases with newly diagnosed MM. The risk of progression to MM is approximately 10% per year for the first 5 years compared to 1% per year for MGUS. Treatment should not be given unless progression occurs.

PLASMA CELL LEUKEMIA

Plasma cell leukemia is defined as the presence of more than 20% plasma cells in the peripheral blood and an absolute plasma cell count $> 2 \times 10^9/L$. When it presents *de novo* (60% of cases) it is classified as primary, and when it presents as a leukemic transformation of a previously recognized MM it is secondary (40%). Patients with primary plasma cell leukemia are younger and have a greater incidence of hepatosplenomegaly and lymphadenopathy, fewer bone lesions, a smaller serum M component and a longer survival than patients with secondary plasma cell leukemia. Cytogenetic abnormalities are more common than in patients with MM.³⁴ ASCT after response to high-dose chemotherapy has been beneficial for some patients. Those with secondary plasma cell leukemia rarely respond to chemotherapy because they have already received treatment for MM and are refractory.

NONSECRETORY MYELOMA

Patients with nonsecretory myeloma have no M component in either the serum or the urine and account for only 3% of patients with MM. The FLC assay is abnormal in more than 60% of patients and is useful for monitoring response to therapy. The diagnosis is established by identification of an M protein in the plasma cells by immunofluorescence or immunoperoxidase. The behavior of nonsecretory myeloma is similar to MM, except there is less renal involvement.

SOLITARY PLASMACYTOMA OF BONE

The diagnosis of solitary plasmacytoma of bone is based on the presence of a skeletal plasma cell tumor without evidence of MM. The hemoglobin, calcium, and creatinine values are normal, there are no other bone lesions, and the bone marrow contains no increase in monoclonal plasma cells. Small amounts of M protein may be present in the serum or urine, but they usually disappear after tumor-icidal radiation (40–50 Gy). MRI is useful because of the high incidence of MM if additional lesions are seen, in contrast to patients with no additional lesions on MRI.³⁵ Overt MM develops in approximately 55% of patients during long-term follow-up. New bone lesions or local recurrences develop in about 10%. There is no convincing evidence that chemotherapy affects the incidence of conversion to MM. Progression, when it occurs, is usually evident within 3–4 years.

EXTRAMEDULLARY PLASMACYTOMA

The diagnosis is based on the finding of a plasma cell tumor in an extramedullary location and the absence of MM on bone marrow examination, radiography, and appropriate studies of serum and urine. Approximately 80% of cases involve the upper respiratory tract, producing epistaxis, nasal discharge, or nasal obstruction.³⁶

Treatment consists of tumor-icidal radiation. Adjuvant chemotherapy does not appear to lower the relapse rate or increase disease-free survival. Local recurrence is approximately 5% or less if tumor-icidal radiation is given. A review of 400 publications between 1905 and 1997 found 800 cases. Patients who had combined surgery and radiation had better results than those who had only surgery or only radiation. There was local recurrence in 22% of patients whereas MM developed in 15%.³⁶

POEMS SYNDROME (OSTEOSCLEROTIC MYELOMA)

The major clinical findings in POEMS syndrome are characterized by polyneuropathy, organomegaly, endocrinopathy, M protein, and skin changes (POEMS).³⁷ Castleman's disease may also be present. The major clinical findings are chronic inflammatory demyelinating polyneuropathy with predominantly motor disability and sclerotic skeletal lesions. Papilledema may occur. Hepatosplenomegaly and lymphadenopathy may be present. Skin hyperpigmentation and hypertrichosis may be prominent. Gynecomastia, testicular atrophy, and clubbing of the fingers and toes may occur. Pulmonary hypertension has been recognized in several instances. Ascites, pleural effusion, and peripheral edema may be present. The hemoglobin level is usually normal or elevated and thrombocytosis is common. Hypercalcemia and renal insufficiency rarely occur, and the bone marrow usually contains less than 5% plasma cells. Most patients have a λ protein, and IgA is common. The diagnosis is confirmed by the presence of monoclonal plasma cells in an osteosclerotic lesion. Radiation to the localized osteosclerotic lesion usually produces improvement of the neuropathy, but if the lesions are widespread, ASCT should be seriously considered.³⁸

WALDENSTRÖM'S MACROGLOBULINEMIA

WM is a consequence of a malignant proliferation of plasma cells and B-cell lymphocytes producing a monoclonal IgM protein. In a study from the USA, the incidence of WM was 0.3/100 000 in white men and 0.17/100 000 in white women, with approximately 1400 new cases occurring each year. The median age at diagnosis is 63 years; fewer than 1% of our patients are younger than 40 years and approximately 60% are males.³⁹

CLINICAL MANIFESTATIONS

The onset is usually insidious and characterized by weakness and fatigue. There may be oozing from the oronasal area or blurring of vision. Weight loss, fever, and night sweats resembling lymphoma may occur. Peripheral neuropathy, pulmonary infiltration with cough, and dyspnea or skin lesions may be evident. Dyspnea and congestive heart failure may be an

initial finding. In contrast to MM, renal failure, osteolytic lesions, and AL are rare.

Pallor is a frequent finding on physical examination. Hepatomegaly, splenomegaly, or lymphadenopathy occurs in about a third of patients. Hyperviscosity is often present in WM and can produce oronasal bleeding, blurred vision, headache, vertigo, dizziness, sudden deafness, diplopia, or ataxia. Confusion, dementia, and disturbances of consciousness may occur. Clinical manifestations are rarely due to hyperviscosity if the serum viscosity is less than 4 centipoises (normal=1.8). The correlation between the serum viscosity and clinical manifestations is not precise. Clinical symptoms and retinal lesions, including hemorrhages, exudates, and venous congestion, are more important in making a therapeutic decision.

LABORATORY FINDINGS

A normocytic, normochromic anemia occurs in almost all cases during the course of the disease. The hemoglobin and hematocrit values are often spuriously reduced because of the increased plasma volume. The serum cholesterol value is often low. Serum protein electrophoresis reveals a sharp narrow spike or dense localized band consisting of monoclonal IgM. A bone marrow aspirate is often hypocellular, but the biopsy specimen is hypercellular and extensively infiltrated by lymphocytes, plasma cells, and lymphoplasmacytoid cells and mast cells. In contrast to MM, lytic lesions and fractures are found in fewer than 5% of patients.

DIFFERENTIAL DIAGNOSIS

Diagnosis depends on the presence of typical symptoms, physical findings, IgM protein in the serum, and a lymphoplasma cell proliferation of more than 10% in the bone marrow. It must be differentiated from MGUS of the IgM type, smoldering WM, lymphoma, other lymphoproliferative diseases, MM, and chronic lymphocytic leukemia.

PROGNOSIS

The median survival is approximately 5 years. Morel and colleagues have constructed a risk stratification model based on age (≥ 65 years), serum albumin (< 4.0 g/dl), and cytopenias. Patients in the low-risk, intermediate-risk, and high-risk groups had 5-year survival rates of 87%, 62%, and 25% respectively.⁴⁰ Ghobrial et al.⁴¹ developed a prognostic model based on age more than 65 years and the presence of organomegaly as well as β_2 -microglobulin.

TREATMENT

Therapy should be withheld until the patient has constitutional symptoms such as weakness, fatigue, night sweats, weight loss, features of hyperviscosity, anemia, significant hepatosplenomegaly, or lymphadenopathy. Plasmapheresis should be performed based on the patient's symptoms and physical findings, rather than on the magnitude of the viscosity measurement. Therapeutic options include rituximab, the nucleoside analogues, fludarabine, and cladribine (2-chlorodeoxyadenosine), alkylating agents such as chlorambucil or cyclophosphamide, corticosteroids, and ASCT. Thalidomide has been disappointing but trials are ongoing with bortezomib and sildenafil. A detailed review of management of WM has recently been published.⁴²

HEAVY-CHAIN DISEASES

The HCD are lymphoplasma cell-proliferative disorders characterized by the production of an M protein consisting of an incomplete heavy chain devoid of light chains. There are three major types: α , γ , and μ .⁴³

α -HEAVY-CHAIN DISEASE

α -HCD is the most common type and is characterized by the presence of a monoclonal α -chain with extensive internal deletions encompassing the V_H region and the entire first constant domain.⁴⁴ It usually occurs in the second or third decade of life, and about 60% of patients are male. Most have been from the Mediterranean region and Middle East. Gastrointestinal tract involvement is most common and is manifested by malabsorption, with weight loss, diarrhea, and steatorrhea. It is similar to immunoproliferative small intestinal disease (IPSID), but patients with IPSID do not synthesize α heavy chains. Poor hygiene and low socioeconomic status are important risk factors. Rarely, the respiratory tract is involved.

The serum protein electrophoretic pattern shows a broad band in the α_2 or β regions in half of patients and is normal in the remainder. There is no visible spike. The diagnosis depends on the recognition of a monoclonal α heavy chain in the serum, jejunal fluid, or the lymphocytes and plasma cells. The amount of α -chain in the urine is small and Bence Jones proteinuria is absent. The bone marrow is normal. The course of α -HCD is variable but generally progressive. Surprisingly, antibiotics may produce remission. In patients who do not respond to antibiotics and in those with extensive intestinal or mesenteric involvement, chemotherapy with cyclophosphamide, doxorubicin (Adriamycin), vincristine, and prednisone should be given.

γ -HEAVY-CHAIN DISEASE

In γ -HCD, the γ -chain is incomplete, with large deletions of amino acids, including the C_H1 domain and a portion of the V_H1 of the constant region. The median age at diagnosis is over 60 years but several patients younger than 20 years have been recognized. Its clinical picture has been described as a lymphoma-like illness, but its features are variable, ranging from an aggressive lymphoproliferative process to an asymptomatic state.⁴⁵ The most frequent presenting symptoms are weakness, fatigue, and fever. Autoimmune disorders such as rheumatoid arthritis, Sjögren's syndrome, systemic lupus erythematosus, Hashimoto's thyroiditis and myasthenia gravis have been noted.

Normocytic, normochromic anemia is found in 80% of cases. The amount of γ heavy-chain protein in the urine ranges from nondetectable to 20 g/24 hours; more than half of patients excrete less than 1 g of protein. Bence Jones proteinuria is not found. The bone marrow and lymph nodes contain an increased number of plasma cells, lymphocytes, and lymphoplasmacytoid cells. The diagnosis depends on demonstration of a monoclonal γ heavy chain in the serum or urine.

The median duration of survival in a series of 23 patients from a single institution was 7.4 years (range 1 month to more than 21 years).⁴⁵ Therapy with cyclophosphamide, vincristine, and prednisone is a reasonable choice, but if there is no response, doxorubicin should be added.

Table 78.4 Risk stratification model to predict progression of primary amyloidosis

Risk group	Median survival	
	Patients undergoing stem-cell transplantation (months)	Patients not undergoing stem-cell transplantation (months)
Low risk (cardiac troponin level <0.035 µg/l and NT-proBNP level <332 ng/l)	Not reached at 40 months	26.4
Intermediate risk (any one factor abnormal)	Not reached at 40 months	10.5
High risk (cardiac troponin level ≥0.035 µg/l and NT-proBNP level ≥332 ng/l)	8.4	3.5

NT-proBNP, N-terminal pro-brain natriuretic peptide.
 From Rajkumar SV, Dispenzieri A, Kyle RA. Monoclonal gammopathy of undetermined significance, Waldenström macroglobulinemia, AL amyloidosis, and related plasma cell disorders: diagnosis and treatment. Mayo Clin Proc 2006; 81:653–703, with permission.

µ HEAVY-CHAIN DISEASE

µ-HCD is characterized by a monoclonal µ heavy chain in which the V_H domain is absent. Other deletions may also occur. Most patients have a chronic lymphoproliferative process resembling chronic lymphocytic leukemia or lymphoma. A monoclonal peak is found in the serum of 40% of patients. Two-thirds have Bence Jones proteinuria. Increases in lymphocytes, plasma cells, and lymphoplasmacytoid cells in the bone marrow are common. Vacuolization of the plasma cells is an important clue for the diagnosis of µ-HCD, which depends on the demonstration of a µ heavy chain in the serum. The course of the disease is variable; the duration of survival ranges from less than 1 month to 11 years (median, 24 months). Treatment with corticosteroids and alkylating agents has shown benefit.

PRIMARY SYSTEMIC AMYLOIDOSIS

Amyloid consists of rigid, linear, nonbranching fibrils segregated in a beta-pleated sheet conformation which stains with Congo red and shows apple-green birefringence under polarized light. It is composed of the variable portion of a monoclonal light chain, or rarely, an intact monoclonal light chain, and is the result of a clonal plasma cell proliferative disorder.⁴⁶

DIAGNOSIS

The diagnosis requires the demonstration of amyloid deposits which are composed of monoclonal light chains. It should be suspected in patients with nephrotic syndrome, cardiomyopathy with congestive heart failure, axonal peripheral neuropathy, or orthostatic hypotension, and the presence of a monoclonal light chain in the serum or urine. The source of tissue for diagnosis includes subcutaneous fat aspirate (75% positive), bone marrow biopsy (55% positive), or rectum (75% positive). Biopsy of the liver, kidney, heart, or sural nerve is almost 100% positive. The median age is 65 years. Macroglossia, carpal tunnel syndrome, and purpura involving the periorbital area, face, and neck may occur.

Immunofixation of the serum and urine reveals a positive result in almost 90% of patients at diagnosis. The FLC ratio is abnormal in almost all patients with a negative immunofixation.

PROGNOSIS

The median survival was 13 months in 474 patients seen at the Mayo Clinic within 1 month of diagnosis.⁴⁷ On the other hand, the estimated median survival was 40 months for amyloid patients eligible for peripheral stem-cell transplantation.⁴⁸ Median survival of patients with detectable cardiac troponin T (≥ 1 µg/L) was significantly shorter than those with undetectable levels (6 versus 22 months, respectively) (Table 78.4).

TREATMENT

Melphalan and prednisone have been the mainstay of treatment, but the results are not satisfactory. Patients who are not eligible for a stem-cell transplant (three or more organs involved, advanced cardiac amyloidosis, major comorbidities, or poor performance) are offered therapy with melphalan plus high-dose dexamethasone. The conditioning regimen for transplantation consists of intravenous melphalan (100–200 mg/m²).

Organ improvement can be achieved in 50% of patients treated with an ASCT. The mortality is approximately 10% compared to 1% for patients with MM. Patients with end-stage cardiomyopathy may be treated with a heart transplant followed by a stem-cell transplant. Thalidomide plus high-dose dexamethasone is another option,⁴⁹ but thalidomide is not well tolerated in AL.

Tumor immunology and immunotherapy

Michael T. Lotze, Markus Y. Mapara, Carl H. June

79

Cancer in adults is the end-stage of chronic inflammation; in children, the result of progressive genomic instability arising from inborn or acquired genetic lesions.¹ Chapters 76–78 focus on tumors of the hematopoietic system; here we will consider how solid tumors arise and how immune mechanisms play a role, and review the current status and strategies for immunotherapy of both solid and liquid cancers. Adult cancers arise in the setting of chronic inflammation – smoking and associated tumors of the lung, pancreas, and bladder; distal esophagitis and esophageal cancer; solar irradiation with ultraviolet-associated damage and inflammation of the skin and associated carcinogenesis, and many other examples. In this setting, innate immune cells play a role, recognizing stressed cells or undigested cellular contents when cells undergo nonapoptotic or nonautophagic death.² In addition, the adaptive immune response plays a critical role. Not only does it provide a rich source of CD4 and CD8 T-cell effectors that recognize aberrant protein products derived from mutations arising in this setting, but it is also a source of critical regulatory cells and factors limiting the ability of natural killer (NK) and T cells to mediate cancer eradication. Indeed, most recently in the setting of tumors such as colorectal cancer^{3,4} and ovarian cancer,^{5,6} both effector and regulatory T cells (Tregs) have been found to be differentially associated with prognosis.

Like the quasi-species viruses, human immunodeficiency virus (HIV) and hepatitis C virus (HCV), solid tumors acquire genomic instability,^{7,8} generating mutational based neoepitopes, potentially identified in the context of class I and class II major histocompatibility complex (MHC) molecules. Furthermore, genomic, metabolic, and endoplasmic reticulum stress can be recognized by immune cells through expression of cognate molecules such as Rae-1, MICA, and MICB present on ‘stressed’ cells, with evidence of these molecules shed from many epithelial malignancies. Most recently, evidence has emerged for complex pattern recognition molecules sensing stress through release or degradation of matrix components such as hyaluronan or heparin sulfate through Toll-like receptors (TLRs), through NOD1-like receptors (NLRs) sensing excess uric acid concentrations (NALP3) or unknown tumor products through NOD1,⁹ or through RIG-I like receptors (RLRs) sensing uncapped RNA and hepatitis C viral genomes.

Modern immunotherapies have coevolved with our understanding of immune mechanisms and have largely consisted of strategies focusing on: (1) enhancing nonnecrotic cell death; or (2) enhancing immunity through the afferent limb of immunity, promoting generation of an immune response (vaccines, dendritic cell (DC) strategies); or (3) enhancing the efferent limb of the immune response by stimulating cytolytic effectors (interleukin-2 (IL-2), IL-12, IL-18) or disinhibiting these effectors by limiting regulatory or suppressor cells (CTLA-4 antibody; sLAG3; IL-2Ra antibody) and promoting apoptotic death (Fig. 79.1). Perhaps the most successful immunotherapies have been those applying monoclonal antibodies to target her-2-neu in breast cancer or CD20 in the setting of lymphoma.^{10,11} The only approved cytokine therapies at this time represent the cytokines, interferon- α (IFN- α) and IL-2, and there are currently no approved cellular therapies beyond those involved in hematopoietic transplantation.^{12,13} Many emergent therapies promote one or more of these three alternative strategies. An exciting and as-yet unexplored fourth area in modern immunobiology is the focus on mechanisms of cell death, promoting apoptosis and autophagy and limiting necrotic cancer cell death or release/neutralization of the products derived from necrotic cells.^{2,14–17}

■ A BRIEF HISTORY OF TUMOR IMMUNOLOGY ■

Although murine transplantation models initially found that tumors could be rejected, this was subsequently found to be due to allo-incompatibility to MHC molecules. True tumor antigens, recognized by T cells, have now, however, been identified and well validated in both murine and human tumors. The use of nonspecific immune stimulants, initially with the provision of microbial products (Wilhelm Busch, William B. Coley) and more recently hypomethylated DNA have also led to regression of established human tumors.

- Active immunotherapy. Professor Wilhelm Busch (1826–1881) reported several cases of erysipelas associated with tumor regression. The erysipelas material derived from one patient was transferred to

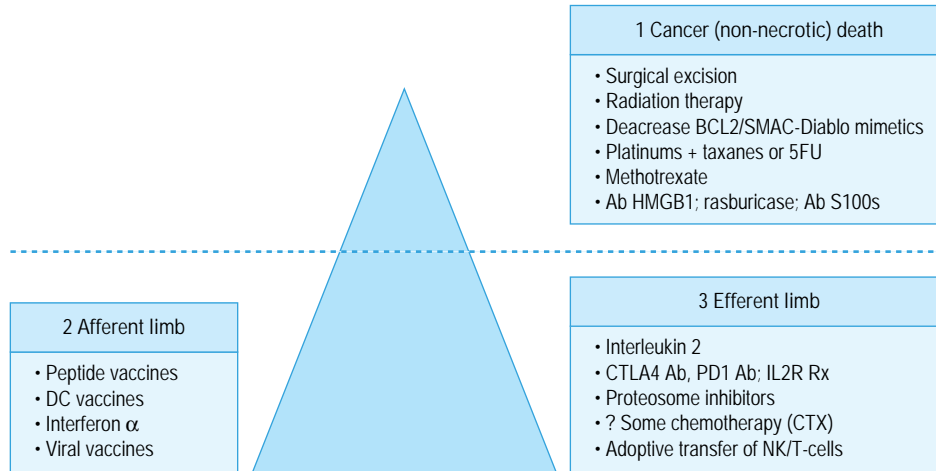

Fig. 79.1 Immunotherapeutic triangle. Traditional therapies for cancer (shown above the dotted line) have involved those designed primarily to (1) kill the tumor cell, largely by mediating necrotic cell death, taking the tumor out or treating with chemotherapy. More recently, it has become apparent that how the tumor cell dies, normally with apoptosis or autophagic death versus necrotic death, is of likely importance. More modern strategies have included use of platinums, which sequester high-mobility group box 1 (HMGB1) in the cytosol, typically in conjunction with taxanes or fluoropyrimidines such as 5 fluorouracil (5FU); radiation therapy, which induces oxidative strand breaks in DNA, limiting necrosis; use of agents such as methotrexate that promote metabolic/autophagic death; or use of means to block anti-apoptotic factors such as BCL2. Antibodies to HMGB1 or S100 proteins or blockade of purine metabolites such as uric acid with enzyme therapies such as rasburicase recognize the critical role of cell death. Below the dotted line are the postulated role of emergent immunotherapies for cancer, which typically focus on enhancing (2) the afferent limb of the immune response through vaccination strategies or application of immune stimulants such as interferon- α or (3) the efferent limb of the immune response with interleukin-2-promoting delivery of immune effectors into the tumor microenvironment, potentiating their cytolytic activity, or use of agents that directly (CTLA4 antibody, or antibodies to other inhibitory pathways) or indirectly (some chemotherapy) limit means of escape from immune detection.

the tumor after heating the skin of the tumor. This was the first clinical experiment in which a purposeful bacterial infection was intended to cure cancer. Subsequently, a New York surgeon, William B. Coley, used a bacterial vaccine to treat inoperable sarcoma, with a reported cure rate of better than 10%.

- **Passive immunotherapy.** Gilliland et al.¹⁸ and Croce et al.¹⁹ demonstrated that monoclonal antibodies could be used therapeutically, ushering in the application for infectious diseases and cancer. Anti-CD20 monoclonal antibodies (rituximab) were approved by the Food and Drug Administration (FDA) in 1997 for the treatment of B-cell non-Hodgkin lymphoma. Addition of rituximab to standard cyclophosphamide, adriamycin (hydroxydoxorubicin, vincristine, concovin), prednisone (CHOP) chemotherapy provided the first improvement in survival in 2002.^{20–22} Transfer of IL-2 activated NK cells to patients with melanoma and other tumors was initially promising but found ineffective in randomized trials; it has had a renaissance in the setting of the treatment of leukemias.²³ More recently, pioneering studies with the adoptive transfer of genetically modified T cells have had demonstrable success with the elimination of large, progressively growing tumors when coupled with lymphodepletion.^{24,25} DC therapies have been associated with anecdotal responses in patients with lymphoma and melanoma.^{26,27}
- **Limiting inhibitory factors.** The notion that immunosuppression and regulatory cells (Table 79.1) played a critical role in cancer has been recognized for many years. That this was derived from tumor

factors, now molecularly defined as transforming growth factor- β and damage-associated molecular pattern molecules (DAMPs, see below) was presaged by Revesz (Fig. 79.2), in pioneering studies performed over half a century ago.^{28,29} He demonstrated that tumors failed to grow in murine recipients unless irradiated tumors were added to limiting numbers of tumor cells. He suggested that the growth-promoting effect was due to: (1) specific stimulation by homologous cell products; (2) provision of a 'feeder effect' in which the dead cells release essential nutrients; or (3) stimulation provoking an inflammatory response and/or vascularization from the host. This notion has relevance today with novel therapies converting necrotic to apoptotic cell death, which paradoxically both recruits immune cells and also drives reparative epithelial proliferation, angiogenesis, and stromagenesis. More recent strategies include the use of antibodies to CTLA-4, thus enabling clonal expansion of T-cell effectors.

Transferable tumor immunity is dependent on T cells, and less dependent on humoral factors. Thus a generation of immunotherapies ensued, predicated on active immunization with antigens and various adjuvants, with little to show for the effort to date. Passive immunotherapies with the application of monoclonal antibodies targeting cell surface molecules and the role of innate immune cells, although thought to be of less importance in previous studies, are now re-emerging, with TLRs, NLRs, and RLRs signaling cell death pathways.^{30,31} Recently the application of histone deacetylase (HDAC) inhibitors to alter gene expression, heat shock protein 90 (HSP90, a critical chaperone protein necessary for the function of many

Table 79.1 Darwinian selection and coevolution of cancer in its host: means of escape from immune control

Host	Tumor	Stroma
Immunosuppressive cytokines/factors (TGF- β , IL-10, PGE ₂ , VEGF)	Immunosuppressive cytokines/factors (TGF- β , IL-10, PGE ₂ , VEGF)	Vascular endothelium in tumor limiting recruitment of host effectors; lack of responsiveness to TNF
Suppressor macrophages	Downregulation of receptors (e.g., TGF- β R)	Nonsenescent fibroblasts
Plasmacytoid dendritic cells producing IDO	Specific downregulation of antigens	Reducing tumor microenvironment
Granulocytes promoting acute inflammatory response	Individual allelic class I MHC molecule expression	Wound repair response to DAMPs (S100 family of molecules, purine metabolites including uric acid and ATP, hyaluronan, heat shock proteins (HSPs), heparin sulfate, and syndecan)
Basophils promoting immunosuppression and angiogenesis	B ₂ -microglobulin loss	
Regulatory T cells limiting immune effectors	Shedding stress receptors such as MICA/MICB	
Blocking antibodies	Tumor antigen loss variants	
Th2–Th4-biased response		

ATP, adenosine triphosphate; DAMPs, damage-associated molecular pattern molecules; IDO, indoleamine 2,3 dioxiygene; IL, interleukin; MHC, major histocompatibility complex; MICA, MHC Class I associated A; MICB, MHC Class I associated B; PGE, prostaglandin E; TGF, transforming growth factor; TNF, tumor necrosis factor; VEGF, vascular endothelial growth factor.

proteins) inhibitors as well as small molecules inhibiting the mammalian target of rapamycin (mTOR, a critical pathway regulating growth, differentiation, and survival in many cancers) in clinical trials suggests that modern small-molecule therapies with defined targets could join biologic agents driving important immune-mediated antitumor effects.

ROLE OF PATHOGEN-ASSOCIATED MOLECULAR PATTERN MOLECULES (PAMPs)

Many tumors arise in the setting of chronic microbial infection. Examples include human papillomavirus and cervical cancer, hepatitis B and C and hepatoma, *Helicobacter pylori*, and gastric cancer. Perhaps the most effective strategies to prevent cancer are those designed to limit infections and resultant chronic inflammation. Indeed, immunization to hepatitis B has been shown to limit hepatoma³² in hepatitis B-carrier children. In those born after initiation of a vaccination program, a lower risk of developing human cervical cancer was identified than those born before the program (risk ratio, 2.3–4.5). Similarly, vaccination to human papillomavirus has led to substantial decreases in cervical carcinoma precursor lesions.³³

ROLE OF DAMAGE-ASSOCIATED MOLECULAR PATTERN MOLECULES

DAMPs are typically released following necrotic and late apoptotic tumor death (Fig. 79.3). DAMPs include the small calcium-binding S100 family of molecules, purine metabolites including uric acid and

KEY CONCEPTS

DAMAGE-ASSOCIATED MOLECULAR PATTERN MOLECULES (DAMPs) AND PATHOGEN-ASSOCIATED MOLECULAR PATTERN MOLECULES IN TUMOR BIOLOGY

- >> Substantial linkage of chronic inflammation with initiation and progression of tumors is found in adults, not in children
- >> Immune cells are found throughout epithelial neoplasms and correlate positively with clinical outcome parameters
- >> Increased high-mobility group box 1 (HMGB1), a prototypic DAMP, is associated with cancer as well as its receptor, receptor for advanced glycation end products (RAGE)
- >> Cancer is associated with release of DAMPs, promoting tumor progression
- >> Decreased incidence of hepatoma is noted in endemic areas where children are vaccinated against hepatitis B
- >> Decreased incidence of cervical intraepithelial neoplasia is noted in women vaccinated against human papillomavirus
- >> Strategies to limit DAMPs in murine models are now in process and could presage novel therapies for patients

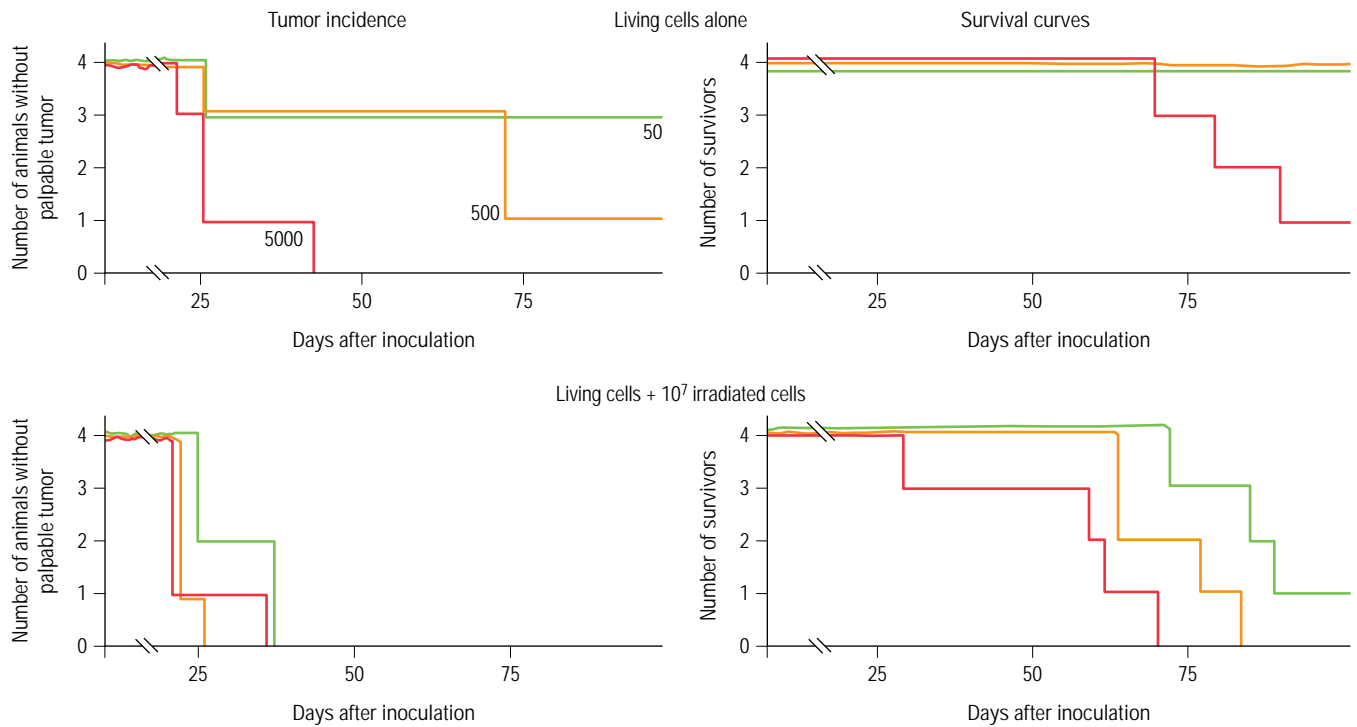

Fig. 79.2 Tumor cell death promotes tumor cell growth. Over 50 years ago, it was recognized that limiting numbers of tumor cells failed to grow in murine hosts unless additional irradiated cells were added. The role of these added cells was considered at the time to mediate its effects by: (1) specific stimulation by homologous cell products; (2) a 'feeder effect' in which the dead cells release essential nutrients; or (3) stimulation through provoking an inflammatory response and/or vascularization from the side of the host. Thus the role of inflammation and immune mechanisms was suggested early as an important part of tumor biology, promoting resultant growth of both primary and metastatic tumors. The factors mediating these effects are recognized today as damage-associated molecular pattern molecules. (Data from Revesz L. Effect of tumor cells killed by x-rays upon the growth of admixed viable cells. *Nature* 1956; 178: 1391–1392.)

adenosine triphosphate, hyaluronan, HSPs, heparin sulfate, and syndecan.¹⁶ An interesting member of the DAMP family which has cytokine-like properties is the evolutionarily conserved nuclear protein, high-mobility group box 1 (HMGB1).³⁴ HMGB1 is present in the nuclei and cytoplasm of nearly all cell types.^{15, 35} It is released upon necrotic but not apoptotic death (Fig. 79.4), and cytolytic effectors promote release from tumor cells.^{14, 35}

ROLE OF INNATE IMMUNE CELLS IN CANCER

Neutrophils and macrophages, particularly M2 macrophages, those promoting wound healing, are associated with poor prognosis. Eosinophils have been found at increased numbers both within tumor tissues and within the bloodstream in cancer patients.³⁶ Eosinophilic granulocytes belong to a class of inflammatory cells that are often found naturally within tumor tissues.³⁷ Eosinophilia is also found following effective immunotherapy and the antitumor effects of successful cytokine therapy of cancer with IL-2 have been associated with the identification of degranulating eosinophils within the tumor.³⁸ In trials of IL-4, Sosman and colleagues³⁹ found induction of systemic eosinophil degranulation with increases in serum and urine major basic protein. Eradication of melanoma metastases⁴⁰ in a mouse model by CD4 Th2 cells is associated with a substantial influx

KEY CONCEPTS

TUMOR BIOLOGY AND THE ROLE OF INFLAMMATION

- >> Cancer arises in the setting of genomic instability
- >> Genomic instability arises from primary critical genetic alterations arising during meiosis and early rapid expansion of the embryo, in a mendelian fashion from the parents, but most frequently in adults as a consequence of chronic inflammation
- >> Pediatric tumors have a paucity of cells associated with adaptive immunity (T cells and myeloid dendritic cells)
- >> Adult tumors are frequently associated with both T-cell and dendritic cell infiltrate
- >> Adoptive immune responses driven by interleukin-2, interferon- α , or dendritic cell therapy can mediate important antitumor effects
- >> Regulatory cells limit immune effector function (M2 macrophages, regulatory T cells, plasmacytoid dendritic cells (PDCs), etc.)
- >> The application of approved immunotherapy for cancer, including the cytokines interleukin-2 and interferon- α , likely promotes adaptive immunity

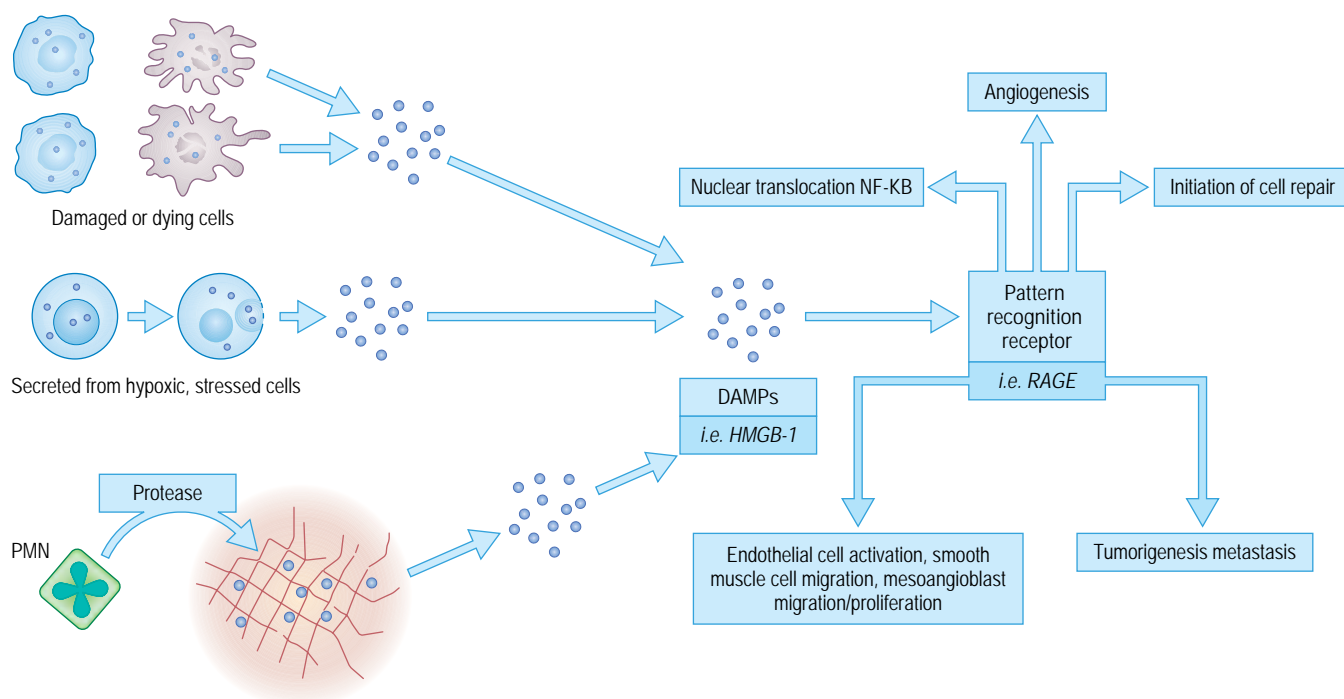

Fig. 79.3 Tumor sources of endogenous damage-associated molecular pattern molecules (DAMPs). In the setting of tumor growth and death, release of DAMPs by damaged or dying cells, actively secreted by hypoxic or stressed cells, or as degradation products derived from proteolytically cleaved tissue matrix, prompted by neutrophils (polymorphonuclear leukocytes, PMNs) collectively leads to recruitment and recognition by innate immune effectors of these products. Together, these changes lead to enhanced survival in viable epithelial cells through upregulation of NF-κB, angiogenesis and stromagenesis, initiation of a wound repair phenotype, and associated with enhanced tumorigenesis, migration, and metastasis.

of eosinophils into the tumor, supporting a role for eosinophil-mediated tumor cytotoxicity. Although incubation of eosinophils with B16 melanoma cells has no direct effects, eosinophil lysates are themselves cytotoxic for tumor.⁴⁰ Understanding the relationship between tumor-derived factors such as HMGB1 and eosinophils is important to discern their role in the tumor microenvironment. Recently, mast cells have been shown to promote survival of allogeneic skin grafts⁴¹ and their perceived role in tumor thus also needs to be immunologically reconsidered.

ROLE OF CANCER STEM CELLS AND MESANGIOBLASTS

Most tissues in humans contain a small subset of cells that self-renew, including solid tumors and hematopoietic neoplasms. During tumor expansion, both inflammatory cells and hemangioblasts are recruited to the tumor microenvironment. Whether tumors arise because of changes in nominal tumor stem cells or whether more differentiated cells acquire stem-cell-like properties is as yet unclear. The goals of developing effective immunotherapies for cancer are similar to those using chemotherapy or radiation therapy. It is unknown whether immune effectors target the nominal daughter cells or the functional stem cells.⁴²

ANTIGEN PROCESSING AND PRESENTATION IN CANCER; RECRUITMENT AND ROLE OF ADAPTIVE IMMUNE EFFECTORS

The notion of cancer immune surveillance suggests that immune cells take an active role in destroying cancers, thereby leading to darwinian selection and emergence of tumors capable of evading immune detection. Indeed, single allelic loss of MHC class I molecules, antigen-processing machinery losses, and even global loss of MHC class I molecules have been noted in cancer (Table 79.1). Presumably antigen-specific T-cell responses to cancer and concurrent alterations in the ability to be recognized by NK cells through stress receptors enable persistence and expansion of malignant lesions. The means to reverse and overcome tumor cell immune evasion is an area of active research.⁴³

WOUND HEALING AND CANCER⁴⁴

The relationship between altered wound healing ('the wound that does not heal') and cancer has been noted for some time. The mechanisms involved and the role of inflammatory and immune cells, however, have been obscure. Fibroblasts can activate an aging process called replicative senescence, possibly providing a barrier against transformation of tissues. The p53 inducible gene plasminogen activator inhibitor-1 is important in replicative senescence, upregulated in stressed fibroblasts,

KEY CONCEPTS

IMPORTANCE OF ANTIGEN PRESENTATION AND ANTIGEN-PRESENTING CELLS (APC) IN CANCER

- >> Tumors are infiltrated with conventional dendritic cells and there is a direct relationship between number of cells and prognosis
- >> Evidence for immune interaction with tumor cells includes loss of single allelic major histocompatibility complex (MHC) class I molecule expression, global β_2 -microglobulin expression loss, or loss of individual elements of the antigen-processing machinery
- >> Tumor cell-derived antigens can be processed and cross-presented by antigen-presenting cells
- >> In murine models, tumors can be immunologically recognized and eliminated by CD8⁺ effectors, even in the absence of class I expression on the tumor cells
- >> Means to increase antigen presentation include application of agents such as interferon- γ or interferon- α to promote protein processing
- >> Means to increase antigen-presenting cells in the tumor include application of agents such as interleukin-2, which increases vascular leak and promotes recruitment of immune cells
- >> Antigen-presenting cells can be increased in number by promoting their production with administration of FLT3 ligand, granulocyte-macrophage colony-stimulating factor, or interleukin-3

THERAPEUTIC PRINCIPLES

IMPORTANT FOR THE IMMUNOTHERAPY OF CANCER

- >> Assess immune reactivity, and the presence of infiltrating immune cells in the peripheral blood and tumor when available; assess presence of necrosis in the tumor
- >> General immune status, delayed-type hypersensitivity (DTH) reactivity to recall antigens
- >> Baseline serum and peripheral blood to assess pretreatment immunity to nominal target antigens
- >> Determine evidence of damage-associated molecular patterns (DAMPs) in the peripheral blood (high-mobility group box 1 (HMGB1), uric acid, lactate dehydrogenase) and DAMP-Rs/induced (soluble RAGE (sRAGE), interleukin-1 receptor antagonist (RA), neopterin)

and inhibiting the urokinase-type plasminogen activator. Senescence, wound healing, and metastasis are thus linked.⁴⁴ The major and crucial roles of epithelia (the origins of most lethal tumors in humans) are: (1) to provide a barrier; and (2) to provide selective transport across that barrier. These are mutually exclusive functions that require guardians, immune effectors that can mediate both tolerance and host defense at this interface. Regulation of the epithelial cell barriers is central to development of immunity and chronic inflammation, and plays a postulated

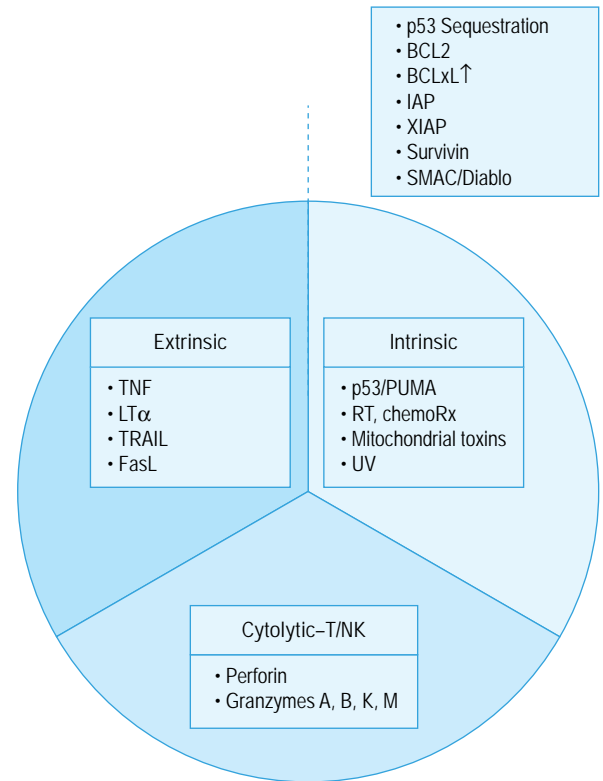

Fig. 79.4 Apoptosis and necrosis in tumor immunobiology. The chevron diagram of apoptotic death involves: (1) intrinsic pathways induced by p53-sensitive induction of cell cycle arrest, and in the absence of genomic repair, upregulation of the BH3 domain containing proteins PUMA and NOXA that promote mitochondrial-mediated cell death and release of SMAC/Diablo and cytochrome C. These are typically induced by radiation therapy, some chemotherapeutic agents, toxins and ultraviolet (UV) irradiation; (2) extrinsic pathways mediated by members of the tumor necrosis factor (TNF) family, including lymphotoxin α (LT α), TNF-related apoptosis-inducing ligand (TRAIL), or Fas ligand (FAS L); or by (3) cytolytic effectors, specifically natural killer (NK) and T cells. Delivery of perforin-mediated pores/membrane disruption and granule exocytosis of the serine proteases, Granzymes A, B, K, and M lead to apoptotic death in normal cells. Paradoxically, in the setting of p53 sequestration in the cytosol, often mediated by mutation, upregulation of the anti-apoptotic proteins, BCL2, BCLxL, IAP, XIAP, and survivin, tumor cells fail to undergo apoptosis or autophagy, but rather, under conditions of genomic, nutrient, or endoplasmic reticulum stress, undergo necrotic cell death. The consequences are release of DAMPs (Fig. 79.3) and resultant recruitment of inflammatory cells. (Data from Zeh HJ 3rd, Lotze MT. Addicted to death: invasive cancer and the immune response to unscheduled cell death. *J Immunother* 2005; 28: 1–9.)

Table 79.2 Examples of tumor antigens applied in cancer immunotherapy

Altered self	Viral antigens	Oncofetal antigens	Autoantigens
K-ras, p53 mutants	EBV-EBNA	Carcinoembryonic antigen (CEA)	Overexpression – c-myc in lymphomas, leukemias
Products of normally unexpressed genes (MAGE, BAGE, GAGE)	HPV E-6,-7	Alpha-fetoprotein (AFP)	HER-2/neu epidermal growth factor receptor- breast cancer (Herceptin)
Proteins of alternative reading frame, of posttranslational modification	SV40 T Ag	Prostate-specific membrane antigen (PSMA) and PSA	
Melanosomal antigens (MART1/ Melan A, gp100, tyrosinase)		Pancreatic oncofetal antigen

central role in cancer development. Several cytokines and other immune modulators that control tight junctions between epithelial cells play important roles during development, wound healing, infection, chronic inflammation, and cancer.

■ IMMUNOTHERAPY OF CANCER ■

ACTIVE IMMUNOTHERAPY WITH VACCINATION

Long-term survival in patients with cancer has changed little in the last 30 years and introducing effective vaccination to cancer patients remains a major therapeutic challenge. Although cancer vaccines have been practiced in animal models for over 50 years, such immunotherapy in patients remains a novel, unapproved approach, which remains experimental. Active specific immunotherapy in patients with various solid tumors has been carried out for the last 10 years with only modest anecdotal response to nominal common tumor antigens (Table 79.2). In part, this may be because each tumor has its own immunodominant antigens, distinct from histologically similar tumors arising in other individuals. Similarly, overall survival obtained by systemic chemotherapy in patients with advanced cancer has been poor, comparable to the low improvement observed with cancer vaccines.⁴⁵ In such trials in 440 patients conducted at the National Institutes of Health Surgery Branch,^{45a} the objective response rate was low (2.6%), comparable to poor results obtained by others. Perhaps the greatest experience has been in patients with melanoma as a consequence of the identification of many melanoma antigens recognized by T cells. Clinical trials performed with various vaccination strategies, including whole tumor cells, antigen peptides, antigen-pulsed DCs, recombinant viruses, plasmids or naked DNA, and HSPs, failed to demonstrate efficacy in the few large phase III randomized clinical trials performed to date.

ACTIVE IMMUNOTHERAPY WITH CYTOKINE TREATMENT

Cytokine therapies are designed to alter immune homeostasis with the tumor and provoke or disinhibit immune effectors. Although both IFN- α (Fig. 79.5) and IL-2 (Fig. 79.6) have been approved for the treatment of patients with metastatic renal cell carcinoma and melanoma, no randomized studies have demonstrated substantial (> 10%) efficacy and the high doses necessary to mediate antitumor effects have substantial toxicities, and thus have precluded widespread acceptance. IL-2 is produced by activated T cells and serves as a growth factor for T and NK cells but also induces sensitivity to apoptosis in these same cells. It induces IFN- γ production and cytotoxicity by T ($\alpha\beta$ and $\gamma\delta$) as well as NK cells. Like IL-2 deficiency, IL-2 administration is associated with enteropathy, whereas the hematopoietin IL-15 that shares two receptors with IL-2 is observed to have gut-protective activity. There have been many clinical trials performed and IL-2 is now FDA-approved for the treatment of patients with metastatic melanoma and renal cell carcinoma. We first showed that IL-2 treatment was associated with substantial gastrointestinal toxicity and rare perforation almost 20 years ago. The pathogenic mechanisms have not been studied in detail. Since therapy with high doses are required to mediate important antitumor effects, toxicity becomes a critical issue, leading to reduction in dose and duration of therapy. However, since the initial report over 20 years ago there have essentially been no improvements in the therapy! IL-2 is associated with major hemodynamic changes, including hypotension, profound oliguria, and renal dysfunction, as well as enteropathy, including:

- Anorexia, nausea, vomiting, diarrhea
- Glossitis, xerostomia, stomatitis

- Colonic necrosis and perforation, increased in patients treated with a combination of IL-2 and IFN- α ; often silent and requiring special attention to findings of free air on abdominal radiographs
- Small-bowel mucosal ulceration and necrosis
- Exacerbation of Crohn's disease
- Rare gastrointestinal hemorrhage
- Reversible profound cholestasis and rare hepatic necrosis

IL-2-deficient (IL-2^{-/-}) mice conversely develop colitis with great clinical and morphological similarities to human ulcerative colitis. The inflamed colons of IL-2^{-/-} mice exhibit a severe disturbance in Na⁺ uptake in the absence of an apparent barrier defect. Reduced expression of active absorptive transport and not a barrier defect is responsible for the diarrhea in this model of intestinal inflammation. Reduced ion transport as well as increased expression of tight junction proteins occludins and claudin-1, -2, -3, and -5 have been noted. Some inflammatory bowel

models are associated with decreases in occludin and claudin-4 expression. Characteristics of inflammatory bowel disease in IL-2^{-/-} mice include:

- CD4⁺CD25⁻ T cells responsible for the pathology
- The inflammatory bowel disease can be 'cured' by injection of CD4⁺CD25⁺ Tregs
- The inflammatory bowel disease is absent in germ-free mice

Although the precise identity of the naturally occurring intestinal Tregs is not known, it is likely that the generation/maintenance of this population is IL-2-dependent and is absent in the IL-2^{-/-} or IL-2R α or IL-2R β knockout mice. The colitis in the mice devoid of IL-2 results in marked infiltration of the colon lamina propria and intraepithelial compartment with CD4 and CD8 T cells. The lytic activity (in a T-cell receptor antibody redirected lysis assay) of these infiltrating cells is low, indicating that other mechanisms of target cell lysis may be utilized by these activated cells. The role of intraepithelial lymphocytes (IELs) in IL-2 or chemotherapy-induced enteropathy has not been examined. *In vitro* lytic activity of IEL (in a redirected lysis assay) is enhanced upon

Fig. 79.5 Time to progression by autoantibody status in melanoma patients receiving adjuvant interferon- α . Immunotherapy for patients with advanced melanoma induces both serologic and clinical manifestations of autoimmunity. In 200 patients enrolled in a larger randomized trial, serum was obtained before the initiation of adjuvant intravenous interferon therapy, after 1 month of therapy, and at 3, 6, 9, and 12 months following therapy. It was tested for antithyroid, antinuclear, anti-DNA, and anticardiolipin autoantibodies, and patients were examined for vitiligo. After a median duration of follow-up of 45.6 months, relapse was observed in 115 patients, and 82 patients died. Autoantibodies and vitiligo were detected in 52 patients (26%). The median relapse-free survival was 16.0 months among patients without autoimmunity (108/148 relapsed) and was not reached among patients with autoimmunity (7/52 relapsed). In multivariate regression analyses, autoimmunity independently predicted relapse-free and overall survival ($P < 0.001$). The appearance of autoantibodies/autoimmunity during treatment with interferon- α_{2b} was associated with statistically significant improvements in relapse-free and overall survival in patients with melanoma. (Data from Gogas H, Ioannovich J, Dafni U, et al. Prognostic significance of autoimmunity during treatment of melanoma with interferon. *N Engl J Med* 2006; 354: 709–718.)

Fig. 79.6 Interleukin-2 (IL-2) treatment-related survival in patients with renal cell carcinoma (RCC) defined by pathologic appearance and carbonic anhydrase (CAIX) model. In patients with RCC, a refined pathology definition of poor risk along with low carbonic anhydrase IX (CAIX) expression was associated with nonresponse to therapy (21/39) in 54% of patients and only 4% of responses. Renal cancer response to IL-2 therapy and patient survival correlate with tumor histology and CAIX expression. Tissue specimens were obtained from 66 patients, 27 of whom (41%) had responded to IL-2-based therapy. Fifty-eight specimens were assessed as clear-cell, with 56, 33, and 4 having alveolar, granular, and papillary features, respectively. Twenty-four (36%), 31 (47%), and 11 (17%) were classified into good-, intermediate-, and poor-prognosis groups according to the Upton pathology model. Median survival was prolonged ($P = 0.04$) and survival > 5 years was only seen in high-CAIX expressers. CAIX expression is a predictor of outcome in renal cell carcinoma patients receiving IL-2 therapy and enhances information obtained from pathology. (Data from Atkins M, Regan M, McDermott D, et al. Carbonic anhydrase IX expression predicts outcome of interleukin 2 therapy for renal cancer. *Clin Cancer Res* 2005; 11: 3714–3721.)

the addition of IL-2, so it is likely that administration of IL-2 can cause lysis of epithelial cells. The mechanism of this lysis is only speculative at this time and the response to the absence or heightened presence of IL-2 is unclear. Although IELs promote mucosal apoptotic death, their absence is associated with predicted heightened mucosal necrotic death and possibly the release of HMGB1, as we have demonstrated in epithelial cell lines. Furthermore, we have recently identified that HMGB1 enhances IL-17 production in murine splenocytes, suggesting a possible role in recruitment of neutrophils and granulopoiesis. In the absence of other inflammatory mediators, we hypothesize that HMGB1, acting to enhance epithelial migration and survival, promotes epithelial survival.

Other systemic therapies, including administration of IFN- γ , IL-1, IL-3, granulocyte-macrophage colony-stimulating factor (GM-CSF)/IL-3 fusion protein, IL-4, IL-7, IL-10, IL-12, IL-18, and TNF- α , have not been demonstrably effective as systemic therapies or as gene therapies. IL-21 is currently in clinical testing. Given the increasing numbers of IL-1 family members, IL-17 family members, and cytokines numbering up to IL-33 factors suitable for testing remain. Still, the likelihood is that advanced neoplasms will unlikely bow to individual or combination cytokine therapies based on the broad experience acquired to date. Prophylactic or adjuvant therapies have not been conducted in sufficient numbers to know whether they might be more effective in this setting.

PASSIVE IMMUNOTHERAPY WITH ADOPTIVE TRANSFER OF T CELLS, NK CELLS, OR DCs

We initially applied IL-2-expanded T and NK cells for therapy over 25 years ago. Transfer of IL-2 activated NK cells was initially promising but it was ineffective in randomized trials. They have had their renaissance in the setting of treatment using *in vivo* expansion of human haploidentical NK cells in patients with cancer.²³ Isolation of antigen-specific cells, *ex vivo* expansion, and subsequent autologous administration continue to be practiced at a few centers. With molecular monitoring of the persistence and transport of transferred cells, this approach has provided some benefit to highly selected patients with metastatic cancer. More recently, pioneering studies with the adoptive transfer of genetically altered T cells demonstrate rather conclusively that most patients are not benefited, but in rare patients, elimination of large, progressively growing tumors when coupled with aggressive lymphodepletion was possible.^{24, 25} DC therapies, which we have championed, have led to responses in patients with lymphoma and melanoma.^{26, 27} DCs can be derived from progenitors in the blood or from bone marrow using combinations of cytokines, particularly GM-CSF (e.g., sargramostim, Leukine) and IL-4. *In vivo* expansion or mobilization with GM-CSF promotes antigen presentation of DCs in the setting of therapeutic cancer vaccine. Once stimulated, DCs can present tumor antigen to naive T cells to initiate an immune response.

PRINCIPLES OF ADOPTIVE IMMUNOTHERAPY

Many lessons can be learned from previous experiments in rodents and humans with adoptive T-cell therapies for the treatment of cancer and chronic infection. The idea that passive transfer of primed immune cells can generate immunity in the recipient is a relatively old idea. First proposed by Billingham, Brent, and Medewar in 1954,^{45b} with the term 'adoptive immunity,' numerous animal studies have demonstrated the effectiveness of this adoptive transfer of immunity toward cancer and

infectious disease, as recently reviewed.⁴⁵ Moreover, adoptive immune cell transfer has the potential to induce long-standing effects via the establishment of immunologic memory.

Two basic approaches are being tested for adoptive immunotherapy (Fig. 79.7). The first approach has been to isolate and activate antigen-specific T cells from peripheral blood or tumor specimens and then clonally expand the antigen-specific cells *in vitro* by various methods.⁴⁶

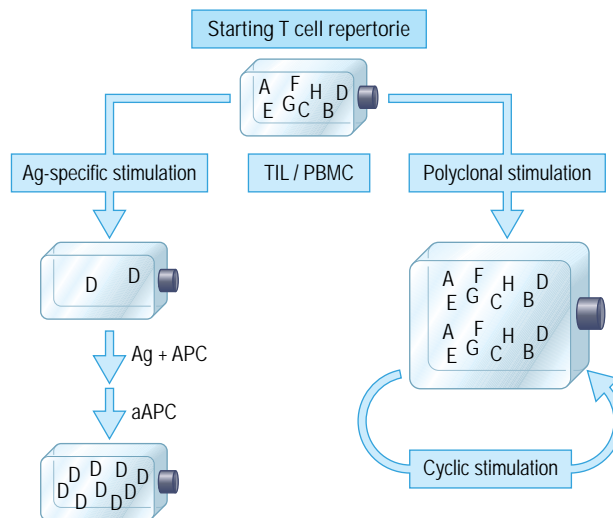

Fig. 79.7 General approaches for *ex vivo* T-cell expansion. Antigen-specific T cells can be generated from the input repertoire by selection of cells with desired specificity with tetramers or antigen-pulsed antigen-presenting cells (APC) and repeated stimulation with APC. This process usually requires several rounds of stimulation (left). Alternatively, the starting T-cell repertoire can be expanded by polyclonal stimulation to generate polyclonal effector T cells. During the culture process, the cells can be manipulated to increase or decrease effector T cells or regulatory T cells (Tregs). In addition, cells can be genetically modified during culture. At least 27 cell divisions are required from a single precursor T cell in order to generate 1 billion clonal T cells. PBMC, peripheral blood mononuclear cells; TIL, tumor-infiltrating lymphocytes.

THERAPEUTIC PRINCIPLES

ADOPTIVE IMMUNOTHERAPY

- >> Avoid induction of immune response to adoptively transferred cells
- >> Prevent or delay cellular immunosenescence
- >> Maximize helper effects
- >> Lymphopenia promotes therapeutic effects of adoptively transferred cells by facilitating niche creation and homeostatic proliferation

In the second approach, polyclonal *ex vivo* activation of the input T cells is done, based on the assumptions that antigen-specific T cells are present in the patient and have been primed *in vivo*.⁴⁷ The first approach will guarantee antigen specificity but is costly and labor-intensive. The second approach is technically more facile. Both approaches have been strengthened by the realization that homeostatic expansion of transferred lymphocytes can improve engraftment and effector functions *in vivo*.⁴⁸ The rationale for the polyclonal approach has been substantially strengthened by the realization that most patients are already primed to their tumor, and that the major issue is improving the quality and quantity of the natural immune response.

Studies conducted during the past several decades have uncovered a number of principles of adoptive immunotherapy. These principles are to: (1) avoid the induction of immunogenicity of the infused cells; (2) prevent or delay cellular immunosenescence; (3) maximize help; and (4) choose lymphopenic rather than lymphoreplete hosts. Given that the immune system is probably the most efficient biosensor system ever developed, it is not surprising that seemingly trivial modifications to cell culture technologies can have large differences in the immunogenicity and subsequent engraftment of the adoptively transferred cells. Human T cells have finite clonal lifespans *in vitro*, a phenomenon also manifested with other somatic tissue cells and commonly known as the Hayflick limit. Lymphocytes and stem cells belong to a select class of cells that have the capacity for induction of telomerase activity. It is possible that many previous clinical adoptive immunotherapy trials have been unsuccessful because the prolonged *ex vivo* culture process resulted in a population of cells that had reached, or were near, replicative senescence. Recent studies show that the *in vivo* persistence and engraftment of tumor-infiltrating lymphocytes (TIL) correlate with telomere length and tumor regression in patients with melanoma.⁴⁹

Many studies show that the generation and/or maintenance of CD8 memory requires CD4 cell help, and clinical adoptive transfer studies show that the persistence of CD8 effector T cells is enhanced with the concomitant administration of IL-2 or CD4 cells. Host lymphodepletion may also enhance the effectiveness of adoptively transferred T cells.⁴⁸ Lymphodepletion eliminates Tregs and other competing elements of the immune system that act as 'cytokine sinks,' enhancing the availability of cytokines such as IL-7 and IL-15. This hypothesis has been tested clinically in patients with metastatic melanoma and myeloma, and initial results suggest that the efficacy of adoptive transfer is improved in patients rendered immunodeficient by cytotoxic chemotherapy.^{50,51}

ADOPTIVE TRANSFER OF EFFECTOR T CELLS

VIRAL SPECIFIC T CELLS

Virally induced lymphomas that retain some expression of the inciting viral genome are likely to present a good target for adoptive cellular therapy. Unlike most spontaneous tumors, the repertoire of T-cell receptors contains T cells with high-affinity receptors for the viral protein, as a consequence of a lack of deletion of these T cells in the thymus. In patients recovering from allogeneic bone marrow transplantation, a severe defect in the cellular immune system exists, and this often results in the death of the patients from reactivation of systemic cytomegalovirus (CMV) or Epstein-Barr virus (EBV) infection. Donor-derived,

CMV antigen-specific CD8 cytotoxic T lymphocytes (CTL) have been administered to the patients, and represents a promising means of restoring immune function.⁴⁶ Even relatively modest doses of T cells (1×10^6 cells/kg) have been shown to be an effective treatment or prophylaxis for patients with EBV-associated lymphoma, with complete remissions recorded in most patients.⁵² Pneumonitis and tumor swelling with respiratory obstruction have been reported as adverse events following CTL infusion for lymphoma. Recent studies indicate that EBV-specific CTLs are safe and have significant antitumor activity in Hodgkin's disease and nasopharyngeal carcinoma associated with EBV infection.

TUMOR SPECIFIC CYTOTOXIC T CELLS

Due to recent technical advances that permit the generation of tumor-specific CTLs, their clinical utility has not yet been extensively evaluated. Tumor-specific CTLs generated *ex vivo* with the rapid expansion method appear to have substantial activity in melanoma, as 8 of 10 patients with refractory, metastatic melanoma had minor, mixed, or stable responses.⁵³ However, studies at the National Cancer Institute suggested that host conditioning can increase the response to adoptive immunotherapy with TIL.⁵⁰ Adverse effects included opportunistic infections, and the frequent induction of vitiligo and uveitis, presumably due to autoreactivity by TIL. If confirmed, these results indicate that prior host immunosuppression is useful to improve antitumor efficacy of adoptive immunotherapy.

T REGULATORY CELLS (TREGS)

Suppressor or Tregs were recently rediscovered based on their ability to prevent a number of autoimmune disorders in mice. A congenital deficiency of FoxP3 in humans leads to a deficiency of Tregs and is associated with a variety of autoimmune immunopathologies.⁵⁴ Tregs were initially thought to be hypoproliferative; however, recent studies show that they can be expanded *in vitro* sufficiently for potential adoptive therapy approaches.⁵⁵ Tregs have not yet been tested in humans; however, based on preclinical studies, graft-versus-host disease (GvHD) following allogeneic hematopoietic stem cell transplantation in adults is likely to be the initial setting for the first human trials with *ex vivo* expanded and adoptively transferred Tregs.

NATURAL KILLER CELLS

Unlike T cells, NK cells are cytolytic for targets, even in the absence of MHC class I expression (Chapter 18). Another hallmark of NK cells is that they use a variety of nonrearranging receptors to initiate cytolytic activity and cytokine production. The ability of NK cells to kill tumors that have diminished MHC class I expression predicts that immunotherapies based on adoptive NK cell transfer should be synergistic with T-cell-based therapies, in that MHC loss variants that emerge as a result of tumor immunoediting by T cells could be 'cleaned up' by NK cell-based approaches.

The availability of recombinant IL-2 enabled the first clinical trials of adoptively transferred autologous NK cells. Due to poor efficacy, adoptive therapy with NK cells was largely abandoned until recently. However, given the recent appreciation that NK cells express both activating and inhibitory (KIR) receptors, a resurgence of interest has occurred.

KEY CONCEPTS

ADOPTIVE IMMUNOTHERAPY WITH GENETICALLY MODIFIED LYMPHOCYTES

- >> Antigen specificity can be assured by transduction of chimeric artificial receptors or natural antigen receptors
- >> T-cell lifespan can be regulated by incorporation of conditional suicide genes or genes to delay senescence
- >> T cells are efficiently transduced with retroviruses and lentiviruses
- >> Genetically modified T cells can be used to study engraftment and trafficking of adoptively transferred T cells
- >> Genetically modified T cells have been shown to persist for years in patients after adoptive transfer

Infusions of 'alloreactive' NK cells have been shown to mediate antileukemic effects against acute myelogenous leukemia in the setting of mismatched transplantation when KIR ligand incompatibility existed in the direction of GvHD, i.e., MHC class I KIR ligand that is absent in the recipient but present in the donor.⁵⁶ Studies indicating that alloreactive NK cells are cytotoxic for melanoma and renal cell cancer cells *in vitro*⁵⁷ suggest that HLA-mismatched hematopoietic stem cell transplantation may be an attractive setting to exploit NK-cell adoptive therapies for patients with solid tumors. Once the complexity of the NK system is better understood, it is likely that clinical trials using combinations of tumor-specific T cells and NK cells will be done.

GENETICALLY MODIFIED LYMPHOCYTES

Genetic modification of T cells *ex vivo* to engineer an improved antitumor effect is an attractive strategy for many settings.⁵⁸ The advent of lentiviral vectors has greatly increased the efficiency of T-cell engineering, and adoptive therapies with HIV-based lentiviral engineered T cells has shown promise in pilot clinical trials.⁵⁹

A number of issues can be addressed with genetically modified T cells to overcome limitations of natural lymphocytes. The first use of genetically modified T cells was to demonstrate that adoptively transferred cells could persist in the host and traffic to tumor. A second use has been to address the principal limitation of cancer immunotherapy, which is tumor-induced tolerance that results in few natural T cells that have high avidity for tumor-specific antigens. To address this problem, some clinical trials now in progress attempt to endow T cells with novel receptor constructs by introduction of 'T bodies': chimeric receptors that have antibody-based external receptor structures and cytosolic domains that encode signal transduction modules of the T-cell receptor.⁵⁸ These constructs can function to retarget T cells *in vitro* in an MHC-unrestricted manner.

Lamers and colleagues recently reported interim results of a pilot trial testing T bodies in 3 patients with metastatic renal cell carcinoma.⁶⁰ The T bodies, expressed in autologous T cells using retroviral transduction, were retargeted with a single-chain Fv fragment specific for carboxyanhydrase-IX (the G250 antigen) that is overexpressed on clear-cell kidney cancers. The subjects were treated with a dose escalation scheme of G250-modified T cells and recombinant IL-2. Infusions of these

G250 T bodies were initially well tolerated; however, significant liver toxicity developed that appeared to reflect expression of the G250 antigen in the biliary tract. This finding points to the promise of genetically retargeted T cells and provides a reminder that expression of the targeted antigen on tissues other than the tumor can result in significant toxicity.

Infusions of genetically modified T cells have also been tested in patients with HIV infection. CD4ζ is a genetically engineered, MHC-unrestricted chimeric receptor composed of the γ subunit of the CD3 T-cell receptor, the cytoplasmic domain involved in signal transduction, fused to the transmembrane and extracellular domains of human CD4, which targets HIV env expressed on the surface of infected cells. Upon binding to HIV envelope, CD8 T cells engineered to express the CD4ζ fusion protein proliferate and initiate effector functions such as cytokine secretion and HIV-specific cytolytic activity. In phase I and II trials, CD4ζ-modified T cells were detected in the peripheral blood of all patients following infusion, and sustained mean levels of 1–3% of T cells were detected for about 1 year after infusion. In a randomized phase II trial, adoptive transfer resulted in modest antiviral effects.⁶¹

GvHD is associated with a potent antitumor effect. The ability to terminate GvHD at will without the use of pharmacologic immunosuppressants following allogeneic T-cell infusions would be useful. Genetically modified T cells that have an inducible 'suicide switch' have been tested in patients after allogeneic hematopoietic stem-cell transplantation. Using this strategy, Bonini and colleagues found that some cases of severe GvHD could be aborted after infusions of allogeneic T cells that had been modified to incorporate this novel conditional suicide switch.⁶² Together these clinical results indicate that genetically modified T cells have promise in early-stage clinical trials in patients with cancer and HIV infection. The principal limitation of most strategies that use genetically modified T cells is that the cell transduction process can render the cells immunogenic, resulting in host-mediated elimination of the adoptively transferred cells.

PASSIVE IMMUNOTHERAPY WITH BONE MARROW TRANSPLANTATION

Harnessing the immune system for induction of antitumor responses has been a long-standing dream and goal of generations of immunologists. In fact the successful introduction of monoclonal antibody therapy for the treatment of lymphomas, as demonstrated by anti-CD20 therapy, has proven that immunotherapy of tumors has become a reality. However, in contrast to monoclonal antibody-mediated immunotherapy, induction of autochthonous T-cell-mediated tumor immunity has been less successful and remains a formidable challenge similar to the situation in infectious diseases where induction of neutralizing humoral immunity has been more successful when compared to induction of T-cell immunity. The major reasons for this failure to induce or maintain T-cell-dependent antitumor responses involve different mechanisms of immune escape, including but not limited to downregulation of MHC molecules, direct tolerization of effector cells or induction of Tregs. Conversely, the concept of immunoediting has been suggested to contribute to the selection of more aggressive, immune-resistant tumor variants.

The power of cellular immunotherapy for the treatment of malignancies has been demonstrated clinically by the success of allogeneic hematopoietic stem-cell transplantation and its associated graft-versus-leukemia (GvL) effects (Chapter 82).^{1,63} In particular this has been proven by the success of the administration of donor lymphocyte infusions (DLI) for the

treatment of relapsed chronic myelogenous leukemia following allogeneic hematopoietic stem-cell transplantation. However, this GvL effect is frequently coupled to the development of GvHD, indicating the relevance of alloantigen versus tumor-associated or tumor-specific antigen recognition by donor T cells as the driving force of GvL reactivity. Furthermore, this notion was supported by the observation that relapse rates following hematopoietic stem-cell transplantation were significantly higher in recipients of grafts from syngeneic twins as compared to HLA-identical siblings.⁶³ HLA-identical siblings invariably differ at multiple minor histocompatibility antigen loci, resulting in an immune response of greater magnitude than that directed against a single or small number of tumor antigens. Since many of these minor histocompatibility antigens are shared by leukemia cells, it is not surprising that these GvH alloresponses against minor histocompatibility antigens are associated with GvL. T cells recognizing allogeneic MHC molecules, as in the setting of non-HLA-identical bone marrow transplants are present at an even higher frequency (approximately 7%) in the unprimed T-cell repertoire of a normal individual.⁶⁴

MHC-MISMATCHED TRANSPLANTATION

Both murine studies and clinical data support the conclusion that T-cell-mediated alloresponses directed against MHC alloantigens lead to even stronger GvL effects than those detected in the setting of MHC identity and minor histocompatibility differences only. Unfortunately, the powerful alloresponse against extensive HLA disparities is associated, as might be predicted, with an unacceptably high incidence of severe GvHD, thus far greatly limiting the ability to exploit this alloresponse for the achievement of maximal graft versus tumor (GvT) effects. However, it has been recently proposed that transplantation across HLA barriers is clinically feasible and can result in potent GvL effects in the absence of GvHD. The strategy ("megadose therapy") which was developed to overcome these barriers and led to the successful transplantation of multiple HLA-mismatched grafts in the absence of GvHD is based on the administration of megadoses of rigorously T-cell-depleted CD34⁺ hematopoietic progenitor cells following a highly intensive conditioning regimen.^{65, 66} Thus, the GvL effects observed in haploidentical transplantations are achieved in the absence of donor T cells and are thought to be mediated by alloreactive donor NK cells.⁵⁶

GvHD is the most prominent complication of allogeneic stem-cell transplantation. The pathogenesis of GvHD is influenced by the immunogenetic disparities between donor and recipient, the presence of host-derived antigen-presenting cells (APCs), and the inflammatory reaction in response to conditioning-induced tissue damage and cytokine secretion. Intestinal damage and subsequent translocation of bacterial products into the circulation are central to the subsequent pathogenic events occurring during development of GvHD. The goal of separating GvHD and GvL has remained rather elusive despite significant progress in understanding the mechanisms underlying the pathophysiology of GvHD. This dilemma became obvious with the finding that depletion of T cells from stem-cell grafts is a very efficient method for preventing GvHD but is also associated with a loss of GvL effect and increased graft failure, underscoring the importance of donor T cells as mediators of GvL effects. Thus, the development of a means of exploiting the GvT effect of anti-MHC alloresponses while avoiding the associated GvHD would be highly desirable. Different approaches have been designed to achieve this goal. These include interfering with the inflammatory host

response, reducing conditioning intensity to minimize the host tissue damage, delaying donor T-cell administration, modulating trafficking of donor T cells, use of Tregs and targeted therapy.

GRAFT-VERSUS-LEUKEMIA EFFECTS

As demonstrated in preclinical studies, the interaction of donor T cells with host APC is central to the development of GvHD,⁶⁷ but also for the induction of GvL effects.⁶⁸ Therefore, approaches aimed at depleting host APCs might mitigate the GvL response. However, there is sufficient evidence that the interaction between host APC and donor T cells is influenced by the presence of a host inflammatory milieu and that the host inflammatory reaction induced by the conditioning treatment is a crucial cofactor for the development of GvHD. Thus, there is ample clinical and preclinical evidence that the conditioning-induced inflammatory response is a key component leading to the development of GvHD.⁶⁹ Notably, donor T-cell-host APC interaction can lead to significant GvL reaction in the absence of GvHD if this encounter occurs in an inflammation-free environment. Therefore, strategies based on prevention of inflammatory reactions (i.e., reduction of conditioning intensity) or interfering with the inflammatory cascade are of the highest interest for the prevention of GvHD.

In recent years significant progress has been made in developing conditioning regimens with reduced conditioning intensity without compromising the engraftment of hematopoietic stem cells, thereby enabling the reduction of the host inflammatory response leading to a decreased incidence of acute GvHD. In fact a broad armamentarium of conditioning regimens is now available, ranging from solely immunosuppressive conditioning regimens to reduced-intensity conditioning regimens to fully ablative regimens, which allow the clinician to choose the conditioning regimen most suitable for the underlying malignancy. It has become obvious that conditioning intensity, which is equivalent to the direct cyto-reduction intensity, is important for malignancies with a high proliferative potential (e.g., acute leukemias), whereas more indolent or slower-growing malignancies like indolent lymphomas or myelodysplastic syndromes are more amenable to true nonmyeloablative conditioning regimens.⁷⁰

MODULATING THE TRAFFICKING OF ALLOREACTIVE T CELLS

The primary aim is to prevent donor T cells from migrating into GvHD target tissues, which include skin, liver, and the intestinal system, while retaining them in the lymphohematopoietic system. At least preclinically, this has been achieved with several approaches. One is to administer DLI to established bone marrow chimeras late after bone marrow transplantation, at a time point when the conditioning-associated proinflammatory response had disappeared. Indeed, rodent studies using mixed chimeras demonstrated that the delayed administration of nontolerant donor lymphocytes resulted in conversion from mixed hematopoietic chimerism to full donor chimerism without any associated GvHD. One possible explanation for this observation is that inflammation in the GvHD target tissues plays a major role in directing the migration of GVH-alloreactive T cells into these tissues, and that, in the absence of this inflammation (e.g., after sufficient time has passed for it to subside), the alloresponse will remain within the lymphohematopoietic system, where leukemias and lymphomas reside. Another approach focuses on

the role of chemokines and their receptors to inhibit infiltration of donor T cells into GvHD target organs⁷¹ or to prevent their exit out of the lymphohematopoietic system.⁷²

CRITICAL ROLE OF TREGS IN GVHD AND GVL

The demonstration that Tregs are key regulators of the immune response and that Treg cells can inhibit GvHD without mitigating GvL in pre-clinical models⁷³ has sparked considerable interest in utilizing these cells for the prevention of GvHD in the clinical setting.⁷⁴ A novel field of investigation to inhibit GvHD is based on the new developments and better understanding of molecular signaling pathways occurring in inflammatory processes and during early GvHD induction in both host tissues and effector cells. Recent preclinical studies have focused on inhibition of NF- κ B (using proteasome inhibitors)⁷⁵ or HDAC.⁷⁶ Both proteasome and HDAC inhibitors prevent or reduce development of GvHD while maintaining GvL responses. However, proteasome inhibition resulted in converse effects – mitigation or enhancement of GvHD – depending on the scheduling of the drugs,⁷⁷ underscoring the complexity of the signaling pathways in the development of GvHD as these inflammatory pathways might also be important for tissue repair. Therefore, further studies are needed to define the precise role of these pathways in GvHD.

CONCLUSIONS

Cancer in adults represents the end-stage of chronic inflammation, often subclinical and thus without symptoms. As such, three strategies, focusing on mediating and enhancing apoptotic or autophagic death of tumors, induction of an afferent immune response, and enhancing and promoting an effective or disinhibited efferent response, represent the three mainstays of cancer immune-based therapy. Combinations of selected cytolytic agents, cytokines, adoptive transfer of T cells/DCs or bone marrow, informed by an understanding of the mechanism of cell death with afferent and efferent immunotherapy strategies, will promote tumor elimination and drive resultant homeostasis in the host.

Concepts and challenges in transplantation: rejection, immunosuppression and tolerance

Barry D. Kahan

80

Although transplantation as a cure for disease is richly described in mythic literature, its clinical practice spans only six decades. The legendary exchange of hearts by the Chinese practitioner Pien Ch'iao restored the proper balance of Yin and Yang elements in each recipient; the xenotransplantation of the elephant's head onto the boy, creating the god Ganesha, corrected the mistaken decapitation by the Hindu deity Shiva; and the limb transplant from the cadaveric Ethiopian gladiator to their devout sacristan by the Saints Cosmas and Damien replaced a gangrenous appendage.¹ The powerful symbolism of the chimeric patient in whom diseased organs are replaced by normal ones represents not only the pantheistic ideal of renewal and 'rebirth' of the recipient, but also the immortality of at least remnants of a frequently unexpectedly and catastrophically terminated donor life.

The barrier to transplant success remained a mystery until this century, when the local resistance 'athrepsia' theory of Ehrlich, which had been reinforced by Loeb's concept of incompatible protein templates, was superseded by the observations of Jensen, Schoene, Holman, and, most elegantly, by Medawar, that rejection was due to acquired immunity:¹ foreign grafts confer a state of donor-specific systemic resistance transferable by lymphocytes and abrogated by neonatal exposure. Our current failures to ensure graft success and to achieve full host rehabilitation are due both to gaps in our knowledge of the immunological events, and to a lack of understanding of the pathophysiology of transplanted organs.

■ ALLOGRAFT REJECTION ■

IMMUNE MECHANISMS

Antigenic signals

The transplant presents a mosaic of antigens foreign to the host. Incompatibility for major blood group ABH antigens triggers rapid rejection, due in most cases to the onslaught of natural antibodies. However, if it survives the first month the ABH-incompatible allograft can enjoy survival similar to that of an ABH-compatible transplant. The incompatibility is not absolute: blood group O recipients display far less

violent reactions toward grafts from donors of the ABO-A2 than from the -A1 erythrocyte subgroup.

A second system determining transplant outcome is encoded by the 'classic loci' within the major histocompatibility complex (MHC), which encode surface glycoprotein products (Chapter 5). The human class I MHC genes HLA-A and -B heavy chains complexed with β_2 -microglobulin are assembled with endogenously generated peptide fragments into heterotrimers. Expression on donor-type antigen-presenting cells (APCs) in the graft interstitium – dendritic cells – powerfully triggers CD8 T cells. In contrast, each class II MHC gene (HLA-DP, -DQ, -DR) encodes two polypeptide chains that, upon cytoplasmic assembly, bind exogenous, endocytosed and endosomally processed antigenic peptides for indirect presentation primarily to CD4 T cells (Chapters 6, 7). Determination of the patient's phenotype for the three MHC loci of greatest import to transplant outcomes – HLA-A, -B, and -DR – has evolved from the use of serologic microcytotoxicity reactions to DNA amplification reactions using selective primers. A six-antigen ('full') match ensures that most living related transplant recipients of a postoperative course are free of serious rejection episodes, provided the patient has not been pre-sensitized. Evidence of pre-sensitization would be provided by the presence of cytotoxic antibodies toward donor-type non-MHC antigens encoded by endothelial, tissue or Lewis erythrocyte markers. The undeniable benefit of HLA identity for living related donor transplants may be explained by the fact that not only the HLA-A, -B, and -DR, but also other, as yet incompletely defined, classic and nonclassic MHC genes encoded on the short arm of human chromosome 6 are shared between donor and recipient. However, even these patients require immunosuppression to counter the modest immunogenicity of non-MHC – so-called 'minor'–histocompatibility loci which, in aggregate, can trigger prompt allograft rejection. Only a graft from an identical twin donor fails to evoke alloimmunity, and thus does not require immunosuppression (unless the recipient's original disease was autoimmune in nature).

In contrast, the impact of HLA matching on the survival of cadaveric donor grafts is controversial. Although it is generally believed that there is a hierarchical relation between the number of HLA matches and the rate of graft survival, data from the large US Renal Data System

document little difference between the outcomes of one- versus six-antigen mismatched kidney grafts. The difference in outcomes between six-antigen matched and living versus cadaveric donor transplants probably reflects the impact of antigens not currently detected by available HLA reagents. The variable impact of HLA matching may be obfuscated by three additional factors: chemical microheterogeneity of individual determinants, causing seemingly identical HLA disparities to evoke a spectrum of responses; distinctive host immune repertoires; and inter-individual differences in pharmacodynamic responses to immunosuppressive agents. Indeed, the current approach using several types of agent has substantially reduced the impact of matching on kidney (but possibly not on heart) transplant survival.²

The graft's antigenic mosaic includes a variety of tissue factors. In the past decade, renal-specific antigens have been identified on the surface of proximal tubular cells and on vascular endothelium (with possible specialization on arterial versus capillary versus venous cells). It seems unlikely that these antigens elicit primary immune reactions in immunosuppressed hosts, but the emergence of a rejection episode may trigger their augmented release as well as enhanced immunogenicity of tissue antigens or passenger microbes, producing 'epitope spreading.' Although these immune responses are more likely to affect long-term graft survival/function, they may lead to pre-sensitization that is undetectable using lymphocyte targets in cross-matching procedures (see below). In summary, despite the availability of the organ donor, it has neither been possible to identify the precise antigenic stimulus that incites rejection in every case, nor to predict the type or intensity of the host immune response.

Evolution of host responses to the allograft

Four factors interact to determine transplant outcome: the degree of antigenic disparity between host and donor; the host's ability to recognize and generate a specific immune response toward the differences;

the immunosuppressive regimen; and the condition of the allograft. Just as the graft presents an antigenic mosaic, the host mounts a pleomorphic response directed by a variety of T- and B-cell clones that recruit an array of nonspecific inflammatory mediators. The many alternative pathways not infrequently circumvent the inhibitory effects of immunosuppressive agents. As T cells are the pivotal elements in the induction of both cellular and humoral responses, the major focus of transplantation biology is to identify the switch that determines whether T cells pursue an alloaggressive pathway or the clinically desirable peripheral tolerance cascades-programmed cell death (apoptosis), inactivation (anergy), differentiation into negative regulatory elements (suppression), or balanced chimerism. The chemical nature and presentation form of the foreign antigen, the host's T-cell repertoire, the presence of co-stimulatory cytokine or surface membrane signals, and the array of therapeutic immunosuppressive agents presumably influence the selection of the response mechanism of alloimmunity versus allotolerance.

ISCHEMIA-REPERFUSION INJURIES

The ischemic injuries consequent upon organ retrieval cause ion and water fluxes, cellular and interstitial edema, the generation of reactive oxygen species in concentrations greater than the capacity of inherent salvage mechanisms, and the activation of apoptotic cascades. These processes are compounded by the reperfusion syndrome owing to the effects of the release of multiple chemokines and cytokines, triggered by the process of brain death in the donor prior to organ retrieval, and by the adverse effects on the poorly oxygenated, substrate-deprived graft during cold storage. These pathologic pathways produce vascular effects, not only of constriction, but also of upregulated expression of ligand pairs on lymphocytes and on endothelial cells that promote leukocyte rolling, tethering and emigration: namely, L-, P- and E-selectins, intercellular adhesion molecule-1 (ICAM-1) and α/β integrins, as well as chemokine homing receptors, respectively (Fig. 80.1). Host lymphocytes contact donor endothelial and interstitial dendritic cells, producing an initial and powerful immune stimulus. The cytokines, particularly tumor necrosis factor (TNF)- α and interferon (IFN)- γ , increase expression of MHC

KEY CONCEPTS

VARIABLES DETERMINING TRANSPLANT OUTCOME

- >> Donor-host antigenic disparity
- >> Strength of host antidonor response
- >> Immunosuppressive regimen
- >> The condition of the allograft

KEY CONCEPTS

PERIPHERAL MECHANISMS OF TOLERANCE

- >> Apoptosis
- >> Anergy
- >> Negative regulation
- >> Balanced chimerism

Fig. 80.1 The adhesion-migration paradigm: Events and interdictions. (A) Lymphocytes entering the graft roll based on selectin interactions (SLeX, PSGL-1, P-, E-, and L-selectins) upregulated by TNF- α and/or IL-1. (B) Upregulation of ICAM-1 leads to adhesion to lymphocyte LFA-1. (C) In the presence of chemokines there is selective upregulation of chemokine receptors, which promote adhesion. (D) Diapedesis into tissues.

antigens, augmenting graft immunogenicity; produce endothelial cell dysfunction, causing cytosolic swelling, proliferative and/or cytotoxic effects; and augment the nonspecific inflammatory response of monocytes and granulocytes. All of these antigen-dependent immune and antigen-independent inflammatory processes contribute to the condition of the transplant, and may conspire to delay recovery and impair long-term graft function.

Because of the increasing demand by transplant candidates and the diminishing supply of cadaveric donors, an increasing proportion of organs are derived under 'marginal' circumstances – advanced age, concomitant hypertensive and cardiovascular disease, reduced graft functional reserve, prolonged organ storage, and/or adverse procurement conditions such as a requirement for vasopressors. Thus, antigen-independent inflammatory reactions play an increasing role among the causes of short- and long-term graft failure.

T-HELPER CELL RESPONSES

Foreign alloantigens are presented to host T cells via both direct and indirect pathways.³ Most organs are endowed with efficient interstitial donor-type dendritic APCs capable of providing co-stimulatory signals. In contrast, the liver bears 'nonprofessional' APCs that cannot deliver critical signals, owing either to their failure to produce co-stimulatory cytokines such as interleukins (IL)-12, -1 and -6, or to the absence of the B7 and/or CD40 ligands, which bind CD28 and CD154 co-receptors, respectively (Chapter 13). In addition, the weak primary linkage of host TCRs to donor antigen on APCs requires amplification by co-receptor pairs, including CD8/MHC class I molecules or CD4/MHC class II molecules, lymphocyte function antigen (LFA)-1/ICAM-1, and CD2 (LFA-2)/LFA-3 (CD58), respectively.

The alternate, indirect route of alloantigen presentation demands that host APCs endocytose and endosomally process released donor antigen into peptides, which are assembled with class II MHC molecules. In contrast to the direct route, which triggers a high frequency of allospecific T cells, the indirect route, akin to stimulation by nominal antigens, elicits only a low frequency of cells. The type and intensity of the host response to foreign alloantigens depend on (1) use of the direct and/or the indirect modes of antigen presentation, (2) the potential capacities and activation status of the APCs, and (3) the nature and strength of the cytokine signals.

TCRs are primarily α/β heterodimers that are present on the majority of mature peripheral blood T cells, with γ/δ heterodimers on a smaller number of lymphocytes, many of which do not appear to be classic T cells (Chapter 9). The nature of peptide binding may determine whether the T-cell engagement is stimulatory or inhibitory. The cell surface events involved in signal transduction and T-cell activation are discussed in Chapter 13.

A major function of primed helper T cells is the synthesis of lymphokines – IL-2 and -15 – that predominantly expand T cells; IFN- γ , acting on macrophages; IL-4, IL-5 and IL-7, stimulating B and, to a lesser extent, T cells; as well as IL-10, which may inhibit APCs and CD4 T cells. There is considerable controversy as to whether the progression toward alloaggression versus alloacceptance depends on the lymphokine profile, namely, a preponderance of IL-2/IFN- γ -synthesizing T-helper (Th)1 versus IL-4/IL-10 Th2 elements that are Fc receptor (FcR) positive, negative regulatory cells. However, some recent findings call into question whether this balance generally explains the mechanisms of graft

acceptance. Clearly, the predominant response of naïve hosts to an allograft includes the synthesis of IL-2, TNF- α and IFN- γ , which recruit not only immunocompetent donor-specific elements, but also nonspecific inflammatory cells, which form the majority of cells infiltrating an allograft (Fig. 80.2).

CYTOTOXIC LYMPHOCYTES (CTL)

CD8 T cells, which recognize antigenic peptides displayed on MHC class I molecules, mature into a major cytotoxic effector population. Foreign class I epitopes, presented as intact surface molecules on donor dendritic cells, directly activate CTL. Following antigen recognition in conjunction with a co-stimulatory second and an IL-2 third signal, CD8 cells proliferate and mature into specific alloreactive clones capable of releasing the humoral mediators granzyme (serine esterase), perforin and cytokines, including TNF- α . Alternatively, CTL activation can be interdicted by 'exhaustive' differentiation following 'superantigen' stimulation, by apoptosis upon contact with cognate peptide, or by the negative regulatory behaviors of 'backward' killing of Th cells, fratricide of other CTLs, and bystander killing of inflammatory elements.

CTL activity in naïve hosts is readily demonstrable after *in vivo* (or even *in vitro*) priming. Lymphocytes obtained by fine needle aspiration of allografts proliferate *in vitro*, generating CTL clones that display broad usage of the TCR repertoire, thus confirming the overlapping and redundant nature not only of stimulatory cytokines, but also of alloreactive host elements. Although estimation of the frequency of CTL precursors/mature elements in naïve hosts does not forecast the severity of subsequent rejection events, one stigma of an immune response is an increased CTL frequency. Despite the critical role of donor-reactive CD8 CTLs, it has been impossible to diagnose the presence or to

Fig. 80.2 Mechanisms of target cell destruction during acute rejection. Panel (A) Cytokines produced by delayed-type hypersensitivity T cells (T_{DTH}) recruit granulocytes (PMN) and macrophages (MΦ) to attack graft. Panel (B) Specific Tc cells directly kill targets via TNF- α , granzyme (GNZ), and perforin (PFN). Panel (C) Humoral response includes Abs that directly fix C (CDC) or attach to MΦ to attack graft cells (antibody-dependent cell-mediated cytotoxicity).

Table 80.1 Rejection characteristics of renal allografts

Type	Timing	Symptoms	Time frame of onset	Vector	Histopathology	Treatment	Success Rate of R _x
Hyperacute	<24 h	Fever, anuria	Hours	C-Ab	Polymorph deposition and thrombosis	None	0%
Accelerated	3–5 days	Fever, graft swelling, oliguria, tenderness	1 day	non C-Ab	Vascular disruption with hemorrhage	Anti-lymphocyte reagents	60%

prognosticate the outcome of rejection episodes based on the number of peripheral blood – or even graft-infiltrating – CD8 cells.

B LYMPHOCYTES

Class I antigen-bearing donor cells may serve as APCs to trigger antibody synthesis. Host antidonor pre-sensitization, as a result of prior blood transfusions, pregnancy, or exposure to cross-reactive infectious agents, may presage a poor prognosis. Although donor-directed IgM antibodies produce target cell lysis *in vitro*, they rarely cause graft loss. In contrast, the presence in recipient serum of complement-fixing host antidonor IgG antibodies, particularly directed toward class I antigens – a 'positive cross-match' – represents an absolute contraindication to renal transplantation, owing to its propensity to produce hyperacute rejection. However, liver and heart grafts may be less vulnerable to this outcome.

Clinical rejection responses

The four major forms of allograft rejection are discerned according to time of onset, pathophysiology, and vulnerability to therapeutic reversal⁴ (Table 80.1). Renal allograft rejection is described here as the paradigm, as similar types of immune responses can occur in all organ transplants.

Hyperacute rejection occurs within the first 48 hours of transplantation. The binding of cytotoxic antibodies to vascular endothelial cells produces thrombosis following local complement activation and aggregation of FcR-positive leukocytes (PMN) and platelets onto the antibody-coated endothelial cells. These events are frequently heralded by fever as well as by severe allograft dysfunction and markedly reduced graft perfusion. Because this response is not amenable to treatment, the condition demands emergency removal of the transplant. Histopathologic examination showing polymorphonuclear leukocyte infiltration, particularly in

the glomeruli of renal allografts, confirms an immunologic vector, as opposed to a 'bland' thrombosis resulting from a technical misadventure during the vascular anastomoses.

Accelerated rejection occurs between 3 and 5 days postoperatively and results from deposition of noncomplement-fixing antibodies that act via FcR-positive K cells and monocytes to produce vascular disruption and interstitial hemorrhage. These events tend to evolve rapidly (within a day), resulting in a clinical picture of fever, graft swelling and tenderness, as well as swiftly deteriorating function. Because of the involvement of a cellular vector and the rapid pace of events, anti-lymphocyte antibodies represent the therapeutic cornerstone. In cases where a positive *post-transplant* cross-match is observed, plasmapheresis combined with administration of an anti-CD20 monoclonal antibody (mAb; rituximab) is useful. Frequently, the condition is only partially reversed, with recurrences of increasing severity, until transplant removal becomes the most appropriate option. Hyperacute and accelerated rejections are anamnestic responses, wherein the antibody vector was either in the circulation at the time of, or its production was immediately triggered after, transplantation. In contrast, acute and chronic rejections result from primary immune responses.

Acute rejection generally occurs between 6 and 90 days post transplant, but may begin later in the transplant course, particularly when triggered by patient or physician noncompliance with the immunosuppressive regimen. Mild and moderate acute rejection episodes produce clinical syndromes of progressive graft dysfunction, swelling and tenderness, infrequently accompanied by fever. The characteristic histopathologic appearance includes a cellular infiltrate containing CD8 cytolytic T cells, and a polymorphic inflammatory response elicited by the release of lymphokines by CD4 T cells. Although perivascular lymphocyte collections characteristic of delayed-type hypersensitivity reactions are frequently present, the typical histopathologic lesion results from direct

lymphocyte contact with parenchymal elements, often accompanied by interstitial edema. For example, in the kidney, lymphocyte penetration of peritubular basement membranes produces 'tubulitis,' a lesion that is almost always reversed by administration of large doses of steroids. Severe bouts of acute rejection frequently include a component that produces endovasculitis, with the infiltration of lymphocytes into the vessel wall below swollen, ischemic endothelial cells. Although administration of anti-lymphocyte antibodies may reverse steroid-refractory cell-mediated lesions, some cases show only transient benefit, followed by recurrent acute episodes and evolution to chronic rejection.

Chronic rejection usually appears at least 60 days post transplant. This insidious condition, which is generally believed to be antibody mediated, includes histopathologic features of smooth muscle cell invasion and proliferation in the intima, disruption of the internal elastic lamina, and vascular immuno-oblivation. Interstitial cicatricial changes are also observed, either associated with or independent of the vascular events. Although the molecular mechanisms by which antibodies trigger these changes are uncertain, cytokines, eicosanoids, and growth factors have been documented to participate in the process. In renal transplantation the clinical picture includes vasculopathic hypertension and glomerulopathy with accelerating proteinuria, followed by microscopic and then gross hematuria. The presence of complement component C4d in peritubular capillaries of the kidney seems to represent a footprint of the humoral immune response. When this histopathologic finding is accompanied by the presence of donor-specific antibody in the serum, a combination of plasmapheresis and anti-CD20 mAb therapy may forestall the inevitable loss of the graft. Liver allografts undergo the 'vanishing bile duct' syndrome; heart transplants, a pernicious form of coronary artery disease; and lung transplants, bronchiolitis obliterans. The chronic rejection lesion shows a treatment-resistant, indolent but progressive course of stepwise deterioration of allograft function over a period of months to years.

IMMUNOSUPPRESSION

Immunosuppressive strategies have evolved slowly during the past century, from the cytotoxic agents benzene and toluene to the anti-proliferative modalities of radiation or anti-metabolites, to the present era of disrupting the production, reception and transduction of cytokine

THERAPEUTIC PRINCIPLES

LIMITATIONS OF IMMUNOSUPPRESSIVE THERAPY

- >> Paresis of nonspecific host resistance
- >> Excessive T-cell depression
- >> Collateral toxicities

signals. However, despite this progress, the pharmacologic and antibody reagents currently available are merely nonspecific bludgeons that can engender serious side effects. First, most agents display at least some degree of inhibition of nonspecific host resistance by macrophages, monocytes and polymorphonuclear leukocytes. Second, excessive immunodepression of T and B cells may lead to the emergence of occult viral infections in, or neoplastic diseases of, lymphoid cells. Third, adverse effects on nonimmune organs not infrequently result from the high drug doses that must be administered to achieve adequate immunosuppression. The anti-proliferative and steroid combination used in the original pharmacologic strategies exemplified the first problem; the mAb OKT3, the second problem; and cyclosporine (CsA), tacrolimus (TRL), and sirolimus (SRL), the third. Indeed, in some cases the 'diseases' produced by immunosuppression are of greater consequence than that of allograft rejection: to wit, post-transplant diabetes mellitus engendered by steroids or by TRL. Avoidance of adverse outcomes is currently difficult owing to the lack of assays to quantify the effects of individual immunosuppressive agents; of intermediate immunologic endpoints for early rejection diagnosis prior to tissue damage, and of monitoring reversal to avoid excessive treatment; as well as quantitative, scientifically based individualized algorithms to tailor induction, maintenance and anti-rejection therapies to patient needs. Thus, current clinical practice uses an array of nonspecific therapies of low immunosuppressive or low therapeutic index, rather than strategies that induce donor-specific unresponsiveness.

AGENTS THAT INTERFERE WITH ALLORECOGNITION

Interruption of ischemia/adhesion/migration

Although no agents are currently approved to interdict the initial events in the injury response – leukocyte adhesion and emigration into the graft interstitium – this area represents a major focus for new therapeutic strategies. In experimental animal models some modalities seem to dampen these injuries: endothelin-A receptor antagonists; or molecular antagonists or mAbs blocking selectins, LFA-1, or ICAM-1. However, clinical trials using murine mAb directed against ICAM-1 or LFA-1 failed to show beneficial effects in human renal transplantation. An ongoing trial of a recombinant p-selectin glycoprotein ligand-immunoglobulin conjugate proffers an exciting approach to the problem.⁵ Many of these agents may be delivered initially *ex vivo* to saturate the graft, and then administered continuously in the recipient (Fig. 80.3A).

One new class of agent is the synthetic compounds that bind to type 1 sphingosine-1-phosphate receptors. Patients treated with the archetypal sphingosine analog FTY720 displayed depletion from the

peripheral blood.⁶ Experimental animal studies revealed sequestration of lymphocytes in secondary lymphoid structures – peripheral and mesenteric lymph nodes as well as Peyer's patches. Although in clinical trials FTY720 displayed a pleiotropic array of serious side effects –bradycardia, dyspnea, macular edema and potentiation of calcineurin-inhibitor-induced nephrotoxicity – second-generation compounds with greater selectivity for subtype 1 versus the other four receptor types are in development. Furthermore, this class of agents is stimulating research into the dynamics of entry, residence and release of lymphocytes from thymic and peripheral lymph node sites.⁷

Depletion of graft antigen

A variety of strategies have sought to eliminate 'passenger' dendritic APC elements within the graft and thereby subvert direct allorecognition (Fig. 80.3B). Only modest depletion has been observed after donor pretreatment with a methylprednisolone/cyclophosphamide cocktail administered *in vivo*, or after exposure of the isolated graft to irradiation or to pan-leukocyte anti-CD45 mAbs. In contrast, reducing the T-cell component of bone marrow or small bowel transplants by purging these grafts with large doses of selective lectins, polyclonal sera or mAbs has been shown to improve outcomes, as the donor lymphoid contingent mediates alloaggressive graft-versus-host reactions that are particularly resistant to existing immunosuppressants.

Inhibition of APC function

At present, steroids are used to dampen APC functions (Fig. 80.3C). The complexes of steroids with their cytoplasmic and nuclear receptors interact with glucocorticoid-reactive elements (GRE) within the DNA sequences of a variety of gene promoters, such as the enhancer region of IL-1. However, similar GRE sequences enhance (or repress) the functions of many genes, resulting in what has long been regarded as the Achilles' heel of clinical immunosuppression: the pernicious side-effect profile associated with steroid therapy.

The experimental drug 15-deoxyspergualin (15-DSG; molecular weight 50 kDa) binds to intracellular heat shock proteins (HSP) 40 and 90, which are involved in cytoplasmic shuttling and MHC-loading of peptides. 15-DSG inhibits APC processing and presentation, thereby dampening antigen-specific, but not mitogenically driven, T-cell proliferation. Neither IL-1 nor IL-6 synthesis, nor the expression of B7 or CD28 co-stimulatory signals is reduced by 15-DSG.⁸ However, the compound blocks the secretion of hydrolytic enzymes, the generation of oxygen radicals, the expression of MHC class II surface antigens, and the production of cytokines. Preliminary trials of 15-DSG at doses of 40–220 mg/m² revealed modest clinical activity, primarily for the reversal⁹ rather than the prophylaxis of acute rejection episodes. However, because of the toxicities of leukopenia, thrombocytopenia, nausea, vomiting, anorexia, facial numbness and headache, only short courses of therapy are recommended.

Blockade of surface T-cell receptor/co-receptor molecules (Fig. 80.3D)

A variety of rodent antihuman mAbs have been exploited to bind surface epitopes, either for cell depletion from the peripheral blood, or for 'covering' to prevent interaction(s) critical for T-cell activation. The only Food and Drug Administration (FDA)-approved mAb, OKT3 (Ortho, Raritan, NJ), is an IgG_{2a} mouse mAb directed against the ϵ chain of the pentapeptide CD3 complex. In large doses it purges T cells from the circulation. In the more reasonable 'approved,' 5 mg doses, OKT3 modulates cell function by interrupting the transduction of the TCR signal. Approved for reversal of acute cellular rejection episodes, the agent also delays their onset and reduces their incidence. Thus it may be used as an induction treatment to facilitate recovery from ischemia–reperfusion injury, which may be delayed by other immunosuppressants. However, OKT3 displays toxic effects owing to its propensity to initially activate T cells releasing TNF- α and IL-2 cytokines.¹⁰ The clinical syndrome includes fever, chills, myalgias, dyspnea and aseptic meningitis. Furthermore, OKT3 treatment may be limited by host production of human anti-mouse antibodies (HAMA) that bind to circulating reagent molecules, neutralizing their activity. This obstacle is being addressed by engineering antibodies to contain a majority of human amino acid sequences, particularly in the Fc region, using either F(ab')₂ (chimeric) or only the complementarity-determining (humanized) regions. Alternatively, less toxic mouse isotypes or IgA variants that cannot bind human FcR are being proposed as reagents that do not cause the activation processes seen with OKT3.

A broad array of mAbs reactive with other epitopes are under clinical investigation. The first group is directed toward monomorphic common determinants on human α/β TCR: The T10B9 IgM reagent displays equivalent potency in rejection reversal, but less toxicity than OKT3.¹¹

The IgG_{2b} BMA 031 (Behringwerke, Marburg, Germany) reagent delays the onset and reduces the 30-day incidence of, but does not reverse ongoing, rejection episodes.¹² In contrast to these broad reagents directed against all TCRs, specific anti-TCR idotype reagents have been demonstrated to avert transplant rejection or to reverse autoimmune disease in experimental animal models.¹³ Unfortunately, the pleiomorphic array of TCR idiotypes exploited by various patients in alloimmune rejection responses probably precludes this approach in the clinical setting.

A second group of reagents are directed against APC: T-cell co-receptors that strengthen the antigen-TCR signal denoted as 'Signal 1.' Although anti-CD4 mAbs produce a durable distortion of alloimmunity with consequent transplantation tolerance in rodents,¹⁴ preliminary trials of an anti-CD4A mAb (Ortho) failed to demonstrate benefit in clinical trials. However, dose and schedule considerations warrant further investigation. Because anti-CD8 mAbs produce only modest effects in animal models, they have not been tested in humans. The report of transplantation tolerance induction in mice using a cocktail of two mAbs directed toward the third pair of co-stimulatory markers – ICAM-1/LFA-1 – led to disappointing results in clinical trials using these mAbs individually. Whereas studies in experimental animal models suggested the utility of mAbs directed against CD2, a pan-T-cell marker present both in the resting and the activated states, or against CD7, an activation marker on lymphocytes, these reagents seem to display little clinical promise for effective rejection prophylaxis.

Recent attention has focused on reagents that disrupt co-stimulatory interactions of Signal 2. The administration to mice of an IgG conjugate of a CD28 homolog, cytotoxic T-lymphocyte antigen-4 Ig (CTLA-4Ig; Bristol-Myers Squibb, Ny), disrupts interactions between the APC B7-1/-2 and the T-cell CD28 markers. It only modestly prolonged allograft survival, but did induce tolerance to xenogeneic human pancreatic islets. Furthermore, only at high (40 mg/kg) doses did the agent ameliorate psoriasis in a clinical trial. A new humanized form, LEA29, has been examined in a phase II trial which suggested equal efficacy to, but less toxicity than, CsA.¹⁵ Unfortunately, interruption of the interaction of CD40 with CD154 using anti-CD154 mAbs (Biogen; Boston, MA), which appeared to be even more effective than CTLA-4Ig in experimental animal models, produced an array of thrombotic events, leading to its withdrawal from clinical trials. Alternate approaches using mixtures of anti-B7-1/-2 mAbs or anti-CD40 mAbs are currently in clinical trials.

Agents interfering with cytoplasmic activation from G₀ to G₁: inhibition of regulatory proteins for gene transcription

Despite the numerous and multifaceted independent pathways that mediate initial activation of resting T cells (G₀ phase), only one therapeutic strategy is currently available: to inhibit the Ca²⁺-dependent cascade that generates the regulatory proteins controlling DNA transcription of a range of m-RNAs encoding proinflammatory cytokines, including IL-2, IL-3, IL-4 and IFN- γ . CsA (Sandimmune or Neoral formulation, Novartis, Basel, Switzerland), a fungally derived cyclic endecapeptide of molecular weight 12.2 kDa, and tacrolimus (TRL; FK506; Prograf, Fujisawa, JP), an actinomycete macrocyclic lactone of molecular weight 75 kDa, act via a similar mechanism. Because of their hydrophobic nature, the drugs readily penetrate plasma membranes and bind to the cytoplasmic *cis-trans* prolyl isomerases, cyclophilins and FK-binding proteins, respectively.¹⁶ These complexes inhibit the enzymatic actions of

calcineurin to dephosphorylate and transport the nuclear factor of activated T cells (NF-AT) as well as other transcriptional activators of cytokine genes to the nucleus (Fig. 80.3E).

The introduction of CsA improved 1-year cadaveric renal graft survival from 51% to 88%, and reduced the rate of acute rejection episodes from 85% to 50%.¹⁷ The pharmacokinetic limitations of the original oil-based CsA formulation, including poor oral bioavailability and great inter- and inpatient variability, have been addressed by the introduction of a microemulsion formulation.¹⁸ *In vitro* experiments and *in vivo* animal transplant models suggest that TRL displays a 25–50-fold greater immunosuppressive effect than CsA. TRL and Sandimmune CsA-based immunosuppressive therapy, in conjunction with azathioprine (Aza) and prednisone (Pred), produced equal graft survival rates in renal¹⁹ or liver recipients,^{20,21} although the incidence of acute rejection episodes was significantly reduced, namely 30.7% versus 46.6% ($P=0.001$) in the USA, and 25.9% versus 45.7% ($P=0.001$) in the European multicenter trials, respectively. Size-limited and hence anecdotal experiences in pancreas, heart, and lung transplantation suggest similar results. This benefit has been particularly useful in patients at high risk for rejection, such as African-Americans, or for prophylaxis of reactions against highly immunogenic small bowel grafts.

However, both CsA¹⁷ and TRL display pleiotropic toxicities possibly related to the wide tissue distribution of both calcineurins and drug-binding isomerase proteins. It is unclear whether one agent displays a lesser degree of nephrotoxicity, the major limiting side effect of this drug class. On the one hand, TRL causes a more severe neurotoxicity and alopecia, whereas on the other, CsA causes hypertrichosis and gingival hyperplasia. One alternate strategy has been advocated to reduce the toxicities: a peptide analog of NF-AT that competes with calcineurin action only for this and not for other substrates. However, this approach is unlikely to overcome all of the toxicities associated with CsA and TRL, as NF-AT is expressed in many tissues, including cardiac muscle. Thus, neither NF-AT nor calcineurin is an ideal therapeutic target. It may be anticipated that ongoing biochemical dissection of lymphocyte activation pathways will provide insight into the future design of more selective agents acting in the G₀ to G₁ transition. One candidate is the apparently specific lymphoid cell kinase (lck), which mediates membrane-proximal signal transduction by phosphorylating CD3 ζ -associated protein.²²

Agents interfering with cytokine reception

Because IL-2 is a prominent (albeit neither necessary nor sufficient) vector of rejection responses, anti-IL-2 receptor mAbs have been developed to blockade activation driven by this cytokine. In contrast to the high degree of xenosensitization caused by, and the low efficacy of, the original polyclonal antibodies, humanized²³ or chimeric²⁴ reagents directed towards epitopes on the activation-induced IL-2R α chain display good tolerability and improved rejection prophylaxis (Fig. 80.3F). Two multicenter trials (USA and worldwide) using the same protocol documented that the administration of two 20 mg doses of the mouse-human chimeric mAb basiliximab (Simulect, Novartis, East Hanover, NJ) in combination with CsA and steroids decreased both the incidence (33% basiliximab group versus 48% placebo group; $P=0.012$) and the severity of acute rejection episodes, as well as improving renal function over 12 months.²⁴ Similarly, the addition of five biweekly 1 mg/kg doses of the humanized anti-IL-2R mAb daclizumab (Zenapax, Hoffman-LaRoche,

Nutley, NJ) to a regimen of CsA, Aza and steroids significantly reduced the incidence of biopsy-proven acute rejection within the first 6 months to 28%, compared to 43% for the placebo-treated group in the USA trial (with Aza-Pred) and with 47% in the European cohort (without Aza; $P=0.03$).²³ However, at 12 months patients treated with CsA-Aza-Pred failed to display a benefit of adjunctive daclizumab treatment on either rejection episodes or renal function (Daclizumab Product Insert). The immunosuppressive activity of both reagents is limited by two shortcomings. First, the antibodies do not compete effectively with the IL-2 ligand for binding to the IL-2R. Thus, they must be used in circumstances where IL-2 production is low and cannot reverse acute rejection episodes. Second, the specificity of the antibodies for CD25 (IL-2R α), despite ensuring their reactivity with only activated T cells, does not prevent immune activation generated via other cytokines, such as IL-7 and IL-15, which do not share the α chain and which can be independently recruited to mediate allorecjection in IL-2 knockout animals.

Agents disrupting cytokine-stimulated G₁ activation

Two agents act on the calcium-independent cytokine transduction events during the G₁ phase. Sirolimus (SRL; rapamycin; Rapamune; Wyeth-Ayerst, Princeton, NJ; molecular weight 95 kDa),²⁵ a macrocyclic lactone produced by an actinomycete, forms complexes with the immunophilin FKBP12, thereby inhibiting a multifunctional kinase – mammalian target of rapamycin (mTOR). This inhibition disables transduction of growth and of cytokine signals in the G₁ phase (Fig. 80.3G), both at the relatively early stage of activation of p70^{S6} kinase, and later at the generation of the elongation factor for ribosomal protein synthesis, as well as at steps necessary for cyclin activation. SRL thus inhibits the transduction of a variety of cytokine signals that may promote the vasculo-occlusive phenomena of chronic rejection, namely, the hematologic-vascular stem cell growth factor, vascular endothelial growth factor, and fibroblast derived growth factor, in addition to those of the IL-2 family. However, the broad tissue distribution of mTOR and its participation in a variety of signal transduction processes may explain the dyslipidemic, myelosuppressive and catabolic effects of SRL.

Fig. 80.4 Cytokine paradigm. Complementary sites of action of immunosuppressive drugs during lymphocyte activation. Cyclosporine (CsA) and tacrolimus (TRL) inhibit transcription of T-cell growth-promoting genes (e.g., IL-2). Anti-IL-2 mAbs block binding of IL-2 to its receptor. SRL blocks growth-factor-initiated signal transduction.

SRL acts in synergistic fashion with CsA, owing to its effects on both G₁ progression, and, as recently discovered, the co-stimulatory Signal 2 cascade, namely, blockade of the kinase necessary for generation of c-Rel transcription factors. Thus, we formulated the matrix of CsA, anti-IL-2R mAbs and SRL as the three components of the cytokine paradigm (Fig. 80.4).

Clinical trials have documented the immunosuppressive activity of SRL.²⁶ The pivotal phase III US and global trials showed that the rates of efficacy failure (a composite of the occurrences of acute rejection episodes, graft loss and/or death) were significantly reduced ($P<0.0001$) among patients treated with either SRL 2 mg/day ($n=511$), or SRL 5 mg/day ($n=493$), versus either placebo ($n=130$), or azathioprine (Aza; $n=161$). Furthermore, fewer patients treated with SRL displayed acute rejection episodes that were graded as moderate or severe by the Banff system, or required antibody therapy for rejection reversal. Because of the 90–96% overall patient and graft survival rates, it was not possible to discern a difference in these outcomes among the groups. As is the case for other immunosuppressive agents, higher (5 mg/day) doses of SRL were necessary to show a therapeutic effect in African-American patients.²⁷ The trials confirmed preclinical observations that SRL and CsA are metabolized by the same cytochrome P450 isoforms and extruded from cells via p-glycoprotein, leading to intense pharmacokinetic interactions that exacerbate each other's toxicities. The major clinical concern is the potentiation of calcineurin antagonist-induced nephrotoxicity, which is being addressed by marked reductions in the exposure to CsA by as much as 80% to minimize synergistic pharmacodynamic interactions leading to adverse reactions.

Everolimus (EVL, Certican, Novartis, Basel, Switzerland), a 25-hydroxy-ethyl derivative of SRL, is slightly more hydrophilic than the parent compound and displays a more rapid clearance rate. Like SRL, the analog drug is rapidly absorbed, reaching a maximum concentration (C_{max}) within 2 hours, but, in contrast, EVL displays a half-life of 16–19 hours, which is significantly shorter than that of SRL (30 hours) and thus necessitates twice-daily dosing. EVL concentrations reach steady state by 4 days, in contrast to 7 days for SRL. The pharmacokinetic parameters of both drugs show dose proportionality, with a good correlation between trough and area-under-the-curve (AUC) concentrations. Future studies must gauge whether the EVL analog confers any benefits beyond those achieved with SRL. In a phase I study in stable renal transplant patients²⁸

EVL displayed a similar spectrum of side effects to that observed with SRL, and in a preliminary phase II dose-finding trial, the 2 mg/day EVL cohort showed a similar incidence of acute rejection episodes to the SRL 2 mg/day group.²⁹ However, a phase III multicenter randomized blinded clinical trial showed no benefit of EVL compared to MMF.³⁰ Another ongoing phase III trial is assessing the role of CsA dose minimization to increase the benefits of EVL therapy.

Recently, attention has focused on disrupting membrane-proximal signal transduction events that are relatively specific for the IL-2 family of lymphokine receptors – IL-2, -4, -7, -9, -13, and -15. A nonspecific inhibitor of Lck and Fyn tyrosine kinases of the Src family, the isoxazol derivative leflunomide (Hoechst, Basle, SZ), has been shown to prolong rodent as well as canine renal allograft survival times.³¹ However, its toxic effects in animal models have necessitated caution in *de novo* administration to human transplant recipients. A recently completed trial has confirmed this concern, and so the drug is unlikely to be utilized in future regimens. An alternate target is Janus kinase 3 (Jak3), an enzyme that transduces membrane receptor IL-2R γ -chain activation to signal transduction and transcription (STAT) factors. An ATP analog with modest selectivity for Jak3 versus Jak2 evoked prolonged survival of renal allografts in subhuman primates and is currently in clinical trials.³²

Another target is the protein translation process. The selective class of agents – DNA oligonucleotides (oligos) – bind homologous regions of mRNA, thereby disrupting ribosomal synthesis of a specific protein. Oligos that selectively disrupt TNF- α -driven upregulation of ICAM-1 synthesis have been shown to inhibit *in vitro* proliferation, block expression of this tethering molecule upon perfusion *ex vivo*, and prolong the survival of vascularized heterotopic cardiac or renal allografts in experimental animals. Although the stability of oligos has been enhanced by substitution of sulfonyl for phosphoryl groups, the clinical application of these agents has been limited by their high negative charge, leading to poor cytoplasmic penetration,³³ an obstacle that is being addressed by methoxyethoxy substitutions on the terminal nucleotides.

De novo nucleoside synthesis inhibitors

The slightly reduced activity of purine salvage enzymes in lymphocytes compared to other rapidly dividing cell types suggests that these immune elements are more dependent on *de novo* nucleoside synthesis of DNA and RNA building blocks (Fig. 80.3H). However, the inhibition of *de novo* nucleoside synthesis produces a low immunosuppressive index, because this effect also inhibits a variety of cell types. Azathioprine (Aza; Burroughs-Wellcome, Research Triangle, NC), mizoribine (MZB; Bredinin, Toyo Jozo, Tokyo, JP) and mycophenolic acid (MPA) all inhibit generation of guanosine monophosphate (GMP), thus mimicking the Lesch–Nyhan syndrome. Aza, a competitive inhibitor of a variety of synthetic pathways, including inosine monophosphate dehydrogenase (IMPDH), the target of MPA and MZB, was developed following the pioneering animal work of Schwartz and Dameshek³⁴ using 6-mercaptopurine, as well as the clinical trials of its imidazole analog by Calne et al.³⁵ After 20 years of clinical use Aza was displaced by CsA as the cornerstone of pharmacologic therapy; however, some physicians combine Aza with CsA to enhance the immunosuppressive effect. Although MZB is widely used in Japan, the morpholinylethyl analog of MPA, mycophenolate mofetil (MMF; Roche, Basle, Switzerland) is used throughout the rest of the world, where it is approved for prophylaxis of

acute rejection episodes in combination with CsA. Although nonnephrotoxic, MMF is associated with diarrhea and a spectrum of other gastrointestinal complaints, as well as neutropenia, an increased incidence of cytomegalovirus (CMV) and BK virus infections, and possibly post-transplant lymphoproliferative disease.

Randomized, double-blind, multicenter clinical trials conducted in the USA, Canada, Europe and Australia showed that the addition to CsA and Pred of either 2 g or 3 g daily doses of MMF, compared with Aza or placebo, significantly reduced the incidence and severity of acute renal allograft rejection episodes during the first 6 months.³⁶ However, the addition of MMF showed less effect on African-American than on Caucasian recipients.³⁷ Furthermore, nonblinded studies have reported that MMF provides better prophylaxis of acute rejection episodes than does Aza in the settings of liver, simultaneous pancreas–kidney, heart and lung transplantations. However, MMF treatment failed to improve patient or graft survivals at 1 or 3 years following cadaveric kidney transplantation, suggesting that the drug did not impede the occurrence or the progression of chronic rejection, a clinical observation that does *not* support the preliminary findings claiming benefits in animal models.³⁸

The frequent adverse reactions displayed by patients toward MMF may be overcome with a new enteric-coated formulation of the sodium salt of mycophenolic acid (MPA; Myfortic, Novartis, Basle, Switzerland), which has less tendency to cause adverse gastrointestinal effects, particularly in subjects intolerant to MMF. A 720 mg dose of MPA resulted in drug exposure bioequivalent to that of 1000 mg of MMF. In clinical trials the efficacy and side-effect profile of MPA was similar to that of MMF.³⁹

A second class of nucleoside synthesis inhibitors blocks dihydro-orotate dehydrogenase, the third enzyme in the *de novo* synthesis pathway of pyrimidine. Because of the critical role of UDP sugars in the synthesis of glycoproteins, these agents may possess additional immunosuppressive properties beyond anti-proliferative effects. The original drug of this type was brequinar (BQR; DuPont-Merck, Wilmington, DE); it has been claimed that leflunomide also displays this activity. The occurrence of the principal toxicity of BQR, thrombocytopenia, which correlated with high peak plasma concentrations, proved to be so dose-limiting as to obviate any benefit when added to a CsA/steroid-based immunosuppressive regimen. Owing to their lack of lymphocyte specificity and to their failure to display synergistic interactions that would permit dose reduction of calcineurin antagonists, the nucleoside synthesis inhibitors are unlikely to become permanent members of a T cell-selective immunosuppressive armamentarium.

Lymphocyte depletion agents

Polyclonal anti-lymphocyte xenoantibodies have been the primary reagents to achieve lymphocyte depletion. These agents opsonize lymphocytes, granulocytes and platelets by binding to a variety of human-specific surface markers. The opsonized targets are then eliminated by the reticuloendothelial system. The hallmark of this effect is a decreased number of CD2⁺ lymphocytes. Therapy is generally targeted to reduce the number of CD2⁺ lymphocytes to 15–50/mm³ in peripheral blood. However, dose reductions from the starting amounts of 10–15 mg/kg are frequently necessary because of thrombocytopenia and neutropenia. Whereas equine hosts were initially used to raise antibodies, more potent reagents have been prepared in rabbits (thymoglobulin).

Although the starting doses of the rabbit products are more modest (1.5 mg/kg), their side-effect profile is similar to that of the equine reagents. These reagents have been associated with serum sickness reactions, which have not been consistently anticipated using skin test with dilute antibody. Owing to its lack of initial side effects on administration, a humanized monoclonal anti-CD52 antibody has increasingly been substituted, revealing little evidence of early adverse reactions. However, lymphocyte depletion, particularly prolonged and intense, has been associated with this reagent.

THE CLINICAL IMMUNOSUPPRESSIVE MATRIX

Unfortunately, the current therapeutic matrix is based on empiric rather than scientific foundations. Indeed, despite the widely disparate intrinsic immunogenicity of various organs, the various degrees of donor versus host incompatibility, and the well-recognized inter-individual variations in recipient immunoresponsiveness, transplant centers have tended to employ relatively uniform schedules for initial induction and early maintenance immunosuppressive regimens.

Induction of immunosuppression

The first 2 post-transplant weeks pose the greatest therapeutic challenge, owing to the need to establish adequate immunosuppression promptly and thus avert an acute allograft rejection episode. Although calcineurin inhibitors exert maximal benefit when delivered at the time of antigen presentation, the propensity of the drug to produce renal and/or hepatic dysfunction suggests the need for delayed administration, particularly in cases of poor initial graft function. The brief window provided by anti-lymphocyte antibodies, either monoclonal (anti-IL-2R, anti-CD25, or anti-CD3) or polyclonal, has now been widened by simultaneous treatment with SRL, or to a lesser extent with MMF, both of which tend to be nonnephrotoxic.

We stratify recipients based on putative immunoreactivity, preferring to use anti-IL-2R α mAbs for induction therapy in weak responders, as they do not carry the potentially severe penalties of depletion agents, namely, excessive global immunodepression enhancing the propensity to viral infection and/or post-transplant lymphoproliferative disease (PTLD). Whereas induction immunosuppression with daclizumab and MMF was attended by an almost 50% incidence of acute rejection episodes,⁴⁰ the combination of basiliximab with SRL has permitted extended periods (mean 33 days) of freedom from concomitant CsA treatment, a particularly useful period for recovery of grafts displaying poor initial function (Fig. 80.5). Only 18% of patients experienced acute rejection episodes, which occurred almost exclusively in re-transplant or African-American patients.⁴¹ For these strong responder patients we prefer thymoglobulin induction.⁴² Other workers have advocated induction treatment with the anti-CD52 reagent.⁴³

In the future the induction period will be the stage for selective immunoregulation. Indeed, a recent preliminary report claimed that one injection of anti-CD52 mAb provided a 'window of opportunity' for donor-host interactions, facilitating the induction of 'almost tolerance,' namely, a state of graft acceptance despite only low doses of immunosuppressive agents.⁴⁴ Unfortunately, a recent report of the 5-year follow-up of this cohort failed to document a benefit over conventionally treated patients.⁴⁵

Fig. 80.5 Induction immunosuppression strategies for renal transplantation. **(A)** Regimen for immediate function includes CsA in low doses, SRL, and steroids, with steroid withdrawal. **(B)** Regimen for delayed graft function: α IL-2R mAbs + SRL + steroids, with delayed introduction of low-dose CsA.

CLINICAL PEARLS

ANTILYMPHOCYTE ANTIBODIES

- >> Avoid cytokine release syndrome with pretreatment with anti-inflammatory agents, and by initial administration of small divided doses.
- >> Reduce viral complications with prophylactic ganciclovir treatment.
- >> Biopsy transplant prior to and at the end of treatment.

Acute rejection prophylaxis

The early immunosuppressive regimen from 2 to 12 weeks seeks to avert allograft rejection episodes, as their mere occurrence, particularly if not totally reversed, presages a greatly increased rate of eventual graft loss. During the past decade, whence CsA and TRL were the therapeutic linchpins, successful rejection prophylaxis at least partly reflected the clinician's expertise to deliver adequate doses of the calcineurin inhibitors tailored to achieve target drug concentrations. For example, the initial 8–10 mg/kg CsA oral dose divided as a twice-daily (b.i.d.) regimen, was adjusted thereafter based on measured trough levels. Although a variety of measurement methods/matrices are available, most workers strive for whole blood CsA concentration targets of 175–350 ng/mL, measured with specific mAbs either in an automated fluorescence device (TDx, Abbott, IL) or in radioimmunoassays with ^3H or ^{125}I tracers. The major challenge posed by this dose-finding strategy is the 54-fold inter-individual variation in CsA (and probably TRL) pharmacokinetic parameters and the limited correlation between CsA trough levels and the AUC, a measure of drug exposure during the dosing interval. As pharmacokinetic studies are beyond the expertise of most centers, an abbreviated strategy utilizing a single 2-hour concentration (target ≥ 1600 ng/mL)

CLINICAL PEARLS**CYCLOSPORINE**

- >> Mechanism of action to inhibit proinflammatory cytokine m-RNA synthesis.
- >> Assure adequate levels of drug: use 2-hour or absorptive phase (0–4)/full area under the curve concentrations.
- >> Avoid use in damaged kidney/liver; prefer induction therapy.
- >> Synergistic immunosuppressive effect with sirolimus.

CLINICAL PEARLS**SIROLIMUS**

- >> Mechanism of action to block transduction of virtually every cytokine signal
- >> Nonnephrotoxic: use for induction therapy
- >> Hyperlipidemia, particularly in diabetics, a major side-effect
- >> Pharmacokinetic interaction with CsA (cytochrome P450 3A4; p-glycoprotein)

has been advocated as a method to assure adequate exposure using a CsA-based regimen during the critical drug absorption phase.

Some clinicians seek to compensate for the pharmacokinetic variability by adding 1 g b.i.d. doses of MMF (1.5 g b.i.d. in African-Americans) to augment the immunosuppressive effect of full doses of the calcineurin antagonist. However, this strategy may result in over-immunosuppression. Because SRL acts in synergistic fashion with CsA, combination therapy permits substantial reductions in exposure to each drug, namely, dose ratios of 5–10 mg four times daily (q.i.d.) SRL with 50 mg CsA b.i.d. (C_2 = 200–400 ng/mL). When TRL is used as base therapy, initial oral doses of 10 mg b.i.d. are followed by adjustments targeting an initial trough concentration of 10–15 ng/mL. The addition of SRL to the TRL regimen permits the use of 1–4 mg doses of TRL b.i.d. However, the renal experience has revealed potent pharmacokinetic interactions between SRL and the calcineurin antagonists, which can impair graft function,²⁷ and the early experience in liver transplant patients suggested an increased incidence of hepatic artery thrombosis. These observations combined with the adverse effects of SRL on wound healing and platelet production have limited the drug's use *de novo*.

The strategy of combining steroids with a calcineurin inhibitor is based on both clinical and experimental data. Steroids inhibit generation of the cytokine IL-1, and of inhibitor κ -kinase (IkK)- α , which would be otherwise activated by co-stimulation, thereby generating NF- κ B, a critical transcription factor. Almost all steroid regimens include a massive (250–1000 mg) intraoperative dose of methylprednisolone to dampen graft tissue injury, to drive lymphocytes out of the circulation and away from the allograft, and to blunt T-cell activation. During the immediate post-operative phase, steroid doses are rapidly tapered from 200 mg to 20–30 mg/day, followed by a more gradual taper to 15 mg by 30 days, 10 mg

by 60 days, and 5 mg by 90 days. The use of combination therapy with an array of drugs can facilitate early steroid withdrawal or even avoidance, particularly in patients who show weak immunoresponsiveness.

Immunosuppression to reverse acute rejection episodes

The principles of treatment for rejection episodes are relatively uniform across organs and among transplant centers. Whereas some physicians empirically initiate treatment with increased doses of steroids, most centers demand histopathologic confirmation of an immune injury, owing to the substantial penalties of excessive treatment of an adequately immunosuppressed patient. Steroid regimens combining large IV doses of methylprednisolone with an oral prednisone taper are useful for patients with type I pure cellular rejection. The delivery of IV steroids achieves high plasma concentrations and rapid reversal of symptoms, particularly fever, graft swelling and graft tenderness. The acute risks of steroid therapy include exacerbating or inducing diabetes mellitus, producing gastrointestinal irritation/perforation, and triggering psychoses. Administration of more than 7 g of methylprednisolone within the first 30 days post transplant constitutes a risk factor for patient survival, owing to the pronounced depression of nonspecific host resistance. Recycling of oral steroids tends to follow a twofold slower version of the taper used during the first post-transplant week. It is important to reduce the level of steroids to the pre-therapy dose within 1 month, as long-term administration of high doses predisposes to gastrointestinal bleeding, myopathy, osteoporosis, bacterial/fungal infections and hypertension. The advantages of steroid treatment are the low medication costs and the 90% efficacy of rejection reversal. A growing community of transplantologists advocates 'presumptive therapy' based on the presence of subclinical acute rejection processes detected by surveillance renal biopsies. This treatment has been reported to improve graft outcomes.

Acute rejection episodes that include humoral and cellular components are generally resistant to steroid therapy. They may be treated with OKT3. However, administration of doses >75 mg OKT3 has been associated with the development of PTLD among cardiac transplant recipients.⁴⁶ Furthermore, as discussed above, the production of neutralizing HAMA occurs in nearly 50% of patients following the initial course of OKT3, which may render a patient resistant to a second course of treatment. Thus, before initiating repeat treatment with OKT3, it is useful to rule out the presence of HAMA. The laboratory at the University of Texas at Houston currently uses OKT3 covalently bound to tosylated dynabeads (M-280) to test for the presence of HAMA. The binding of patient serum to the coated beads is evaluated by flow cytometry after incubation with a fluorescein-conjugated goat anti-human antibody (Jackson ImmunoResearch Laboratories, West Grove, PA). For even more potent treatment, a 10–14-day course of thymoglobulin has been advocated by many physicians.

Refractory rejection therapy

There are considerable differences in the timing at which various transplant centers deem a rejection episode to be actually or potentially steroid resistant. For example, acute rejection episodes that display evidence of vascular injury on histopathologic examination are unlikely to respond to steroids. Some workers define a rejection episode as 'refractory' if it does not reverse after steroid treatment, and suggest a benefit of TRL or

MMF in this setting. A few centers believe that the benefits of steroids, even in the setting of mild rejection episodes, are modest, and favor initial treatment with anti-lymphocyte preparations. After 2–5 days of steroid treatment, most centers assess treatment success based on the remission of symptoms or the onset of improved graft function, or histopathologic evidence of remission. In the clinical setting this assessment may be difficult to make. On the one hand, blood chemistry values reflect tissue damage endpoints, which only slowly reverse even after control of the immune process; on the other hand, delay in the delivery of adequate immunosuppression may condemn the graft to failure or severe permanent impairment.

If the response to steroids is deemed inadequate, the physician proceeds to administer an anti-lymphocyte preparation; the two options are anti-CD3 or polyclonal sera. To minimize OKT3 toxicity, the physician strives to obtain modest and graded cytokine release. Our regimen employs a split-dose approach, delivering 1, 2 and 2 mg IV every 8 hours for the first day, followed by 2.5 mg every 12 hours on the second day, and 5 mg/day thereafter. Each dose is administered with an anti-inflammatory pretreatment cocktail of 100 mg hydrocortisone, 50 mg diphenhydramine and 120 mg acetaminophen. Enumeration of the CD3⁺ T cells in the peripheral circulation provides an intermediate endpoint for the efficacy of OKT3 therapy: values of <10% are deemed to represent a good therapeutic effect. In addition to the acute complications of cytokine release, excessive OKT3 therapy predisposes to CMV infections and PTLD despite routine antiviral prophylaxis. Unfortunately, there are no secure algorithms to guide the duration of OKT3 treatment, as the therapeutic effect may be delayed by 7–10 days and the long-term toxic effects by 14–30 days. On balance, OKT3 therapy plays an established role to reverse 80% of steroid-resistant acute rejection episodes.

Deterioration in transplant function during OKT3 therapy may be due to the emergence of host HAMA that neutralize the therapeutic agent. However, in most instances OKT3 failures reflect pharmacodynamic resistance caused by the emergence of immune mechanisms not susceptible to the modulation of T-cell function. In these cases some physicians advocate a switch to treatment with polyclonal xenogeneic antibodies in an attempt to obtain lymphocyte depletion; however, because of the limited possibility of success, and the morbidity associated with an additional course of treatment, this strategy is rarely justified. ‘Refractory’ rejection episodes that fail to respond to a 14- (or preferably 21-) day course of an anti-lymphocyte antibody place the patient at high risk for graft loss. Thus, a rigorous definition of a refractory rejection episode is one that is both steroid and anti-lymphocyte antibody resistant, as documented by the presence of a positive transplant biopsy at the end of these treatments. In this setting addition of SRL to a CsA-Pred⁴⁷ regimen may ameliorate renal function. An alternative therapy is high dose anti-CD52 mAb.⁴⁸

Acute humoral rejection

Increasingly, humoral antibody, particularly of the IgG class, is being recognized as an important, pernicious component of acute rejection in humans. Hallmarks of the process include the presence of endothelialitis and of the complement component C4d, which is a footprint in the peritubular capillaries of the kidney transplant. The diagnosis is robustly confirmed by the detection of circulating donor-specific antibody, although the graft may be a site of deposition, depleting peripheral blood of this reactant. Humoral vectors are rarely dampened by steroid therapy

and only occasionally abrogated by anti-lymphocyte antibodies. Whereas plasmapheresis can temporarily reduce the antibody content in serum, B cells rebound with the generation of more of this vector. In the past, cyclophosphamide treatment engendered severe myelotoxicity. More recently, intravenous immunoglobulin has been administered with variable outcomes.⁴⁹ Recently, a chimeric murine human anti-CD20 mAb (Rituximab) has been used off-label without or with plasmapheresis, showing benefit in 24 of 27 patients.⁵⁰

LONG-TERM MAINTENANCE IMMUNOSUPPRESSION

Although calcineurin inhibitors without or with concomitant MMF administration have reduced the incidence and severity of acute rejection episodes, they have not improved the 5% annual rate of graft attrition previously observed with Aza-Pred therapy. Although it is possible that this failure reflects chronically inadequate or variable CsA exposure owing to reductions in the calcineurin antagonist doses in response to impaired renal function, it is more likely that the host B-cell responses that mediate chronic rejection are less sensitive to these agents than T-cell responses.

Owing to a lack of knowledge concerning the pathophysiologic mechanisms of chronic rejection, long-term immunosuppressive regimens, including CsA, TRL, steroids, MMF, Aza and SRL, show greater inter-center variations than do the short-term strategies. In the chronic rejection setting, long-term SRL administration may confer novel advantages based on the capacity of this agent to block the effects of hematologic–vascular cytokines that stimulate endothelial and smooth muscle cell proliferation, resulting in immuno-obliterative lesions. Although there are currently no data to support this hypothesis, four observations suggest that SRL may prevent the occurrence or slow the progression of chronic rejection.⁵¹ First, SRL inhibits growth factor-driven proliferation of endothelial and smooth muscle cells *in vitro*, presumably by blocking the action of cytokines critical to producing the immuno-obliterative vascular and bronchial lesions – the histologic hallmarks of chronic rejection. Second, SRL exerts a beneficial effect on the smooth muscle and endothelial cell responses to vascular injury provoked *in vivo* by balloon catheter injury or observed in aortic allografts. Third, SRL mitigates chronic rejection in rat renal allografts. Fourth, used in combination with CsA in humans, SRL reduces the incidence of acute rejection episodes, which are widely believed to predict an increased risk of chronic rejection. Further, the administration of SRL permits either minimization or elimination of CsA, thereby promoting renal recovery during the early postoperative period and possibly mitigating chronic CsA-induced renal dysfunction, which may exacerbate other processes that contribute to graft attrition.

Although the usual strategy is to attempt steroid withdrawal at the patient’s request, where there is good HLA matching or evidence of drug-induced morbidities, the clinician’s decision must be based on a perception of the safety of steroid withdrawal. Evidence of host anti-donor hyporesponsiveness in mixed lymphocyte cultures, cell-mediated cytotoxic effector and precursor assays,⁵² and suppressor ‘three cell’ reactions have provided indices to withdraw steroids from or otherwise modulate CsA- or TRL-based regimens. A delay in withdrawal may compromise some of the potential benefits to be gained from a steroid-free regimen, specifically the prevention of cataract formation, amelioration of diabetes mellitus, and mitigation of bone destruction. There

is a general impression that drug doses can be reduced over time owing to 'adaptation' of the graft to the host; this phenomenon has been attributed to repopulation of the donor vasculature with host elements. However, transplantation of long-term accepted grafts in experimental animals back into syngeneic donor-strain animal hosts fails to elicit rejection responses, a finding that suggests that the host rather than the donor 'adapts' to this artificial situation. However, virtually every patient who discontinues all immunosuppressive medications rejects the graft; there is currently no clinically applicable strategy to induce tolerance.

■ TRANSPLANTATION TOLERANCE ■

IMMUNO-UNRESPONSIVENESS

The ultimate goal of transplantation research is to achieve selective tolerance toward donor – but not third-party – foreign allografts. Tolerance is the 'cure' for transplant success, whereas immunosuppression is only palliative therapy. One must distinguish tolerance from immuno-unresponsiveness, a state that demands at least some concomitant immunosuppression. Although treatment of experimental animals with relatively abbreviated courses of immunosuppressants produces a propensity towards tolerance, such an evolution occurs only rarely in humans. The presence of donor-type putatively dendritic elements in numerous tissues of organ transplant recipients has been attributed to the presence of an unresponsive state,⁵³ indicating a 'truce' between host-versus-graft and graft-versus-host reactions. These findings led to the suggestion that the facile acceptance of liver grafts reflects their rich passenger cell component. This hypothesis has not yet been supported by clinical trials: infusion of supplemental donor bone marrow elements concomitant with transplantation of passenger cell-poor cardiac or renal allografts, or even rich orthotopic liver transplants, has neither improved graft survival nor rendered patients tolerant of their grafts.⁵⁴ Indeed, the significance of chimerism as a marker for unresponsiveness is controversial; some patients displaying donor cell chimerism have been reported to undergo rejection episodes. Calne and colleagues⁵⁵ offer a more conservative proposal: after T-cell depletion with an anti-CD52 mAb, a 1-day interval is allowed to elapse before treatment is started with low-dose CsA in the absence of steroids. These workers suggested that the modest (18%) incidence of rejection observed within 1 year reflected 'prope' (almost) tolerance; however, as noted above, the 5-year data did not show unique benefits in this patient cohort.

Immunological tolerance

The concept of immunologic tolerance evolved from observations that hosts exposed to foreign cells during fetal/neonatal stages subsequently accepted donor-type tissue transplants.¹ In 1914, John Murphy reported that duck or pigeon embryos permit the unrestricted growth of Rous chicken sarcoma cells, unless the embryo had been previously inoculated with adult chicken lymphoid cells. Owen in 1945 demonstrated that nonidentical freemartin calf twins showed erythrocyte chimerism, which he attributed to the exchange of placental blood. Tissue transplant tolerance was demonstrated in fetal or newborn mice by Billingham, in chicken egg embryos by Hasek, and in the first 2 weeks of life of rats by Woodruff.

These phenomena have been explained as an alteration of the 'central' thymic process, which naturally eliminates putatively self-reactive T-cell clones present in the thymus⁵⁵ (Chapter 9). A similar cellular 'macro' chimerism has been produced in adult animals following 'debulking' of the immune system by total-body or total-lymphoid⁵⁶ irradiation to recreate the 'pristine' fetal state and allow 'space' for reconstitution with donor or F₁ bone marrow cells. Adult allogeneic T cells are 'purged' from the donor bone marrow inoculum with anti-T cell sera, with anti-CTLA-4Ig receptor conjugates,⁵⁷ or with anti-CD40 ligand (-CD154) mAbs⁵⁸ to prevent graft-versus-host disease. Hosts displaying this 'macro-chimeric' type of tolerance show either an absent or an altered T-cell repertoire, presumably owing to the effects of the newly seeded donor-type dendritic cells in the host thymus. Clinical induction of macro-chimerism is limited by the hazards and logistical demands of pre-transplant radiotherapy, as well as by the mature state of the primate thymus, such that donor-specific tolerance is not readily produced by intra-thymic injection of donor materials combined with peripheral lymphoid depletion using polyclonal antisera.⁵⁹

The primary potential mechanism of central tolerance is clonal deletion or elimination. Tolerance toward kidney grafts has been observed in patients who have previously received donor-type bone marrow infusions after myeloablative therapy as the reconstituted immune system is putatively of donor type. Administration of a nonmyeloablative conditioning regimen, including cyclophosphamide, thymic irradiation and anti-thymocyte globulin combined with a short course of CsA, has reportedly induced functional tolerance and sustained anti-tumor responses following combined bone marrow and kidney transplantation from the same donor.⁶⁰ However, this approach has not been successful when the marrow and kidney donors are not HLA identical. Alternative T-cell depletion strategies employing immunotoxin⁶¹ or anti-CD52 mAb⁶² have produced equivocal results even when combined with pharmacologic immunosuppressants.

A critical question for the clinical enterprise is whether tolerance can be produced peripherally without 'debulking' or elimination of the host's immune system. The 'horror autotoxicus' concept of Ehrlich postulated that tolerance is a natural immune process that lymphocytes undergo after leaving the thymus. This 'peripheral' form of tolerance occurs despite the persistence of alloantigen-reactive host T cells, an observation elegantly confirmed in transgenic models. The expression of foreign I-E class II molecules restricted to the acinar pancreas and kidney,⁶³ or to pancreatic islet β cells, failed to elicit rejection responses, although adoptive transfer of naïve T lymphocytes killed the transgenic cells.⁶⁴ Durable tolerance in clinically relevant settings probably requires a combination of strategies that affect central and peripheral mechanisms. In humans, several vectors block the emergence of tolerance toward transplants: nonspecific immune responses triggered by tissue injury, the high frequency of alloreactive cells in the repertoire, and cross-reactivity due to recognition of heterologous antigens that generate memory cells which are resistant to depletion or inactivation.

Several mechanisms may explain post-thymic 'peripheral' unresponsiveness: anergy,⁶⁵ ignorance,⁶⁶ deletion by apoptosis⁶⁷ or regulatory (suppressor) cell activity.⁶⁸ Anergy represents an unresponsive state of antigen-reactive lymphocytes. Bretscher and Cohn⁶⁹ proposed that unresponsiveness was due to the absence of an appropriate second humoral activation signal. Th cells recognize alloantigen, but neither proliferate nor secrete IL-2, the addition of which reverses the anergy. Although in animal models anergy emerges after abrogation of helper-inducer

function using nonspecific bludgeons, such as massive doses of a single or multiple mAb(s) in combination with CsA, or, alternatively, high CsA doses alone, this progression has not been documented in humans. On the one hand, anergy may result from ineffective stimulation by modified antigen, for example following treatment with immunogens modified by crosslinking fixation or by planar membrane array. On the other hand, anergy can be produced by direct contact of immature T or B cells with antigen in the absence of co-stimulatory signals, such as due to treatment with anti-B7 or CD154 mAbs or CTLA-4 Ig. The critical role of the Th cell-generated cytokine signals was documented by the failure of B cells expressing the transgene-encoded membrane immunoglobulin to secrete antibody upon confrontation with the corresponding chicken lysozyme epitope. Anergic cells appear to have a propensity towards apoptosis, particularly when the induction strategy – for example anti-B7 mAbs – is combined with a pro-apoptotic drug such as SRL (but not CsA or TRL).⁶⁷ Anergy is unlikely to be operative in humans owing to the wide array of immune stimulants other than alloantigen. These factors would incite cytokine production that would override any ‘anergy strategy.’

The ‘infectious’ tolerance mechanism suggests that lymphoid ‘regulatory’ cells adoptively transfer unresponsiveness. Qin et al.¹⁴ observed that treatment with large amounts of anti-CD4 mAb elicited a novel negative regulatory response, which they propose is integral to the differentiation repertoire of all cells. Regulatory cell activity has been implicated in seven other tolerance models. Animals rendered neonatally tolerant to class II MHC antigens show a higher frequency of tolerogen-reactive lymphocytes than normal mice *in vitro*, yet *in vivo* their cells transfer unresponsiveness but neither cytotoxicity nor delayed-type hypersensitivity to naïve mice. Total lymphoid irradiation (TLI) treatment induces both donor-specific and -nonspecific negative regulatory elements. ‘Debulking’ strategies of tolerance induction using cyclophosphamide produce initial deletion, followed by regulatory mechanisms. Regulatory cells mediate the unresponsiveness produced by anti-lymphocyte serum combined with bone marrow, as well as by high-dose CsA treatment, particularly in combination with extracted antigen. Finally, regulatory T cells – possibly of the CD4 phenotype – mediate classic humoral unresponsiveness associated with ‘enhancing’ antibody. The demonstration of transfer of tolerance with CD4⁺ CD25⁺ T cells from rats bearing long-term surviving cardiac allografts has been amplified by reports of a variety of cell types mediating the process and putative markers of this propensity, among which *foxp3* has attracted the most attention. The mechanisms by which these elements dampen immunoresponsiveness include production of the negative regulatory cytokines IL-10 and TGF- β ,^{70, 71} upregulated activation via the immunodepressive surface molecules GITR or CTLA-4, blockade of receptors on antigen-presenting cells, and inhibition of dendritic cell maturation.⁷² Observations in experimental animals have not predicted results in the human setting: for example, long-term administration of a refined Signal 2 blocking antibody LEA29 failed to yield fewer rejection episodes than conventional CsA-based treatment.¹⁵

Clinical trials to induce tolerance demand that the manipulation be performed within the context of appropriate baseline immunosuppression so as not to jeopardize patient outcome if the strategy is unsuccessful. This requirement presents two potential obstacles: first, the possible inhibitory effect of the immunosuppressant to prevent lymphocyte differentiation along a tolerogenic pathway; and second,

the extreme caution that must be exercised in the withdrawal of baseline immunosuppression, particularly in view of the lack of a validated assay to document the tolerant state. Thus, the present success of the clinical transplant enterprise in addition to the redundancy of plasticity of immune responses in humans creates seemingly daunting obstacles to the exploration of specific immunologic tolerance.

THE FUTURE

Because our knowledge of the immunologic processes that trigger allograft rejection is limited, the clinical success of the transplant enterprise seems outrageous. However, this success has been achieved at the price of appreciable patient morbidity, usually owing to excessive immunosuppression, frequently administered in overzealous treatment of non-existent or mild/moderate alloimmune reactions. The tenuous balance between dampened host resistance and the threat of viral/fungal pathogens, as well as the pleiotropic array of drug toxicities, almost inevitably leads clinicians to reduce the degree of immunosuppression, a measure that is often followed by the emergence of chronic rejection. Thus, the recent spectacular improvements in cadaveric donor transplant outcomes have been short-term rather than long-term; only a minority of patients retain their grafts for 10 years. A more secure strategy seems to be forthcoming with the use of synergistic drug combinations, such as CsA/SRL.

Incisive dissection of alloimmunity in humans demands the development of quantitative indices of graft function, diagnostic tools to detect alloresponses, and reliable surrogates of the pharmacodynamic effects of as well as pharmacokinetic interactions between immunosuppressive agents. These indices could be used to shape an era of hypothesis-testing clinical research that moves the present ‘art’ of transplant care to firm scientific foundations, and brings us to the eventual goal to immunodeviate alloaggressive host responses toward allotolerance. Thus, transplantation offers a fertile field for basic and applied investigation by clinical immunologists.

Challenges and potentials of xenotransplantation

Marilia Cascalho, Jeffrey L. Platt

81

Xenotransplantation refers to the transplantation of living cells, tissues, or organs from individuals of species into another species. Among the various fields of transplantation, none has sparked greater excitement and none greater controversy than xenotransplantation. This chapter will consider the various applications that have been proposed for xenotransplantation, as it is these from which the excitement derives. The chapter addresses the hurdles that prevent the application of xenotransplantation for the treatment of disease today, particularly those hurdles stemming from the immune response of the recipient to the graft. It is from these hurdles and the possibility that xenografts might serve as a vehicle for transfer of infectious organisms between species that the controversy derives.

■ APPLICATIONS FOR XENOTRANSPLANTATION ■

Although various types of xenografts were contemplated and even tried during all of history, xenotransplantation was first undertaken in the early years of the 20th century for the treatment of renal failure. Experimental surgeons had recently devised the vascular anastomosis as a way of connecting the cut end of blood vessels, and that advance created the field of vascular surgery. The vascular anastomosis would allow the repair of traumatic wounds and the penetration of surgery deeper into body cavities. However, those who developed the procedure realized the vascular anastomosis might also prove to be the critical technical advance needed to replace a sick organ with a healthy one, i.e., for organ transplantation.¹ As exciting as the prospect of organ replacement seemed to be, it was not clear then how one could obtain an organ from a human for transplantation. It was reasoned then that since some cellular components of the kidney and other organs often remain alive long after a person is deceased, harvesting a kidney from a cadaver would be unethical. Because of this concern, the first application of the vascular anastomosis to replacement of organ function was conducted using animals – swine and sheep – as a source of organs instead of humans.

The most important reason for interest in xenotransplantation today is to provide a plentiful source of organs, in lieu of human

organs, for transplantation. By some estimates, the number of human organs available for transplantation equals as little as 5% of the number needed.² In the case of the kidney and liver, this shortage may be blunted by the use of living donors. However, for reasons discussed below, the demand for organ transplantation may soon increase further, and dramatically so.

Today, organ transplantation is mainly undertaken to treat severe failure of the kidneys, liver, heart, and lungs. As advances in public health and medicine allow many to live to an advanced age, the prevalence of type 2 diabetes and cardiovascular disease will increase, as will the demand for transplantation. The demand for transplantation could increase further as advances in molecular diagnostics, genomics, and proteomics make it possible to detect tumors and other lethal diseases before they are clinically apparent. The diagnosis of such disease will spark interest in using transplantation to pre-empt these conditions or to spare the patient from the risk of waiting until the tumor can be localized.

Xenotransplantation may even be preferred in some circumstances over human-to-human transplantation. When a virus causes organ failure, xenotransplantation might be preferred to avoid infection of the transplanted organ. This approach has already been attempted for treatment of cirrhosis caused by hepatitis virus and loss of immune competence caused by human immunodeficiency virus (HIV). A xenograft (or at least a xenogeneic organ) might be used as a temporary measure to preserve life or health until healing occurs (or until a human organ becomes available). Thus, the blood of subjects with fulminant hepatic failure has been through swine livers as a way of improving the subject's condition so that the patient could undergo allotransplantation. Xenografts might be used to deliver genes or gene products for complex metabolic pathways, exploiting the ability to express heterologous genes at high levels in genetically engineered animals. Xenografts (human-to-animal) have even been advanced as systems that might coax the differentiation of stem cells into functional tissues and organs.³

Unfortunately, despite the many potential uses and the long history of interest in xenotransplantation, daunting biological barriers presently prevent widespread application of xenotransplantation. These barriers include the graft injury caused by the immune response of the recipient against the graft, physiological incompatibilities between the transplant

and the recipient, and the possibility that the graft might transfer an infectious organism to the recipient. We shall consider all of these barriers, particularly the first.

■ THE SOURCE OF XENOGRAFTS ■

Ideally, xenografts should be obtained from species that are genetically similar to the recipient. Genetic proximity would tend to minimize the immunological barriers to transplantation and might improve the capacity of the graft to function. For human recipients, that ideal source would be nonhuman primates. Table 81.1 lists the outcome of some experimental trials of clinical xenotransplantation. Renal xenografts from chimpanzees functioned up to 9 months in human subjects with renal failure and undoubtedly far better results could be achieved today.

Despite the advantages of minimizing the genetic disparity between the sources and the recipients of xenografts, nonhuman primates are not generally viewed as useful sources of clinical xenografts. Nonhuman primates are not sufficiently numerous and the most abundant are too small in size to provide the organs and tissues needed for clinical xenotransplantation. Also of great concern is that nonhuman primates may harbor infectious agents, particularly viruses, such as herpes B and simian retroviruses, that are incompletely characterized and potentially lethal in humans.

Instead of nonhuman primates, the species that has received the most attention as a potential source of clinical xenografts is the pig. Pigs are available in large numbers and certainly would fulfill any conceivable need for organs and tissues. Pigs are of appropriate size to provide functioning organs for adults. And, because they are born in litters, pigs can be genetically engineered and bred with relative ease. Thus, both transgenic and “knockout” pigs have been developed for xenotransplantation, as discussed below. Finally, the infectious agents potentially carried by pigs are well characterized and, with the exception of an endogenous retrovirus, can be eliminated by scrupulous breeding and housing programs.

■ KEY CONCEPTS

Xenografts excite both innate and adaptive immune responses

The innate response includes xenoreactive natural antibodies, complement, and natural killer cells

The adaptive immune response includes T-cell responses to peptides derived from many xenogeneic proteins plus major histocompatibility complex

The adaptive humoral response includes antibodies against many xenogeneic antigens

The biological outcome of a xenograft depends on the type of graft

Organ xenografts are susceptible to vascular rejection and cellular rejection and are protected by accommodation

Tissue and cell xenografts are susceptible mainly to cellular rejection

■ THE IMMUNOLOGICAL BARRIER TO XENOTRANSPLANTATION ■

As might be expected, many facets of innate and elicited immunity target xenografts. Thus, xenografts engender powerful responses by complement, phagocytic cells, natural killer (NK) cells, antibodies, and T cells. The intensity of these responses was once thought to be a direct function of the phylogenetic distance between the source of the graft and the recipient. However, many of the responses to xenotransplantation are not direct functions of genetic differences, and indeed some of the most daunting responses, particularly by antibodies and complement, can be powerfully exerted between serum and tissue constituents from animal species that are relatively closely related. In the sections that follow, we discuss the components of innate and elicited immunity that recognize and injure xenografts. Following, we shall consider how these components actually injure grafts.

INNATE IMMUNE RESPONSE TO XENOTRANSPLANTATION

Complement

Complement poses the greatest barrier to xenotransplantation, at least for organ xenografts. Once activated in a xenogeneic organ graft, complement can destroy the function and integrity of the graft within a few minutes to hours. This dramatic reaction, called hyperacute rejection, has been used over the years to test for complement inhibitors.

Complement of humans and other mammals can be activated in a xenograft by the alternative pathway or by the classical pathway (Chapter 20). The alternative pathway of complement is regulated on homologous surfaces, but not on some heterologous surfaces, by factor H, which inhibits the association of C3b with factor B. Activation of the alternative pathway of complement appears to provide a primary barrier to xenotransplants between many combinations of donor and recipient species. In some settings, however, for example in transplants of porcine organs into baboons or humans, the alternative pathway of complement is not spontaneously activated, presumably because factor H is functional across these species. In some of these combinations of source and recipient species, xenoreactive natural antibodies, as discussed below, activate complement.

Regardless of which mechanism initiates activation of complement, the kinetics and extent of complement activation is increased due to the lesser ability of complement regulatory proteins to control heterologous complement, a condition called homologous restriction.⁴ Some recent studies have challenged the importance of homologous restriction; however, the observation that xenografts from transgenic animals express very low levels of complement regulatory proteins of the recipient and avoid the most severe types of complement-mediated injury⁵ provides compelling support for the biological importance of homologous restriction and suggests it is limiting for xenotransplantation.

The devising of effective approaches to preventing or controlling activation of complement has been seen for many years as key to the successful application of xenotransplantation. In experimental models, agents such as cobra venom factor, which activates the alternative pathway of complement, and soluble complement receptor type 1 have been found

Table 81.1 Some clinical attempts at xenotransplantation

Year	Donor	Organ	Maximum survival
1906	Pig	Kidney	2 days
1964	Chimpanzee	Kidney	9 months
1964	Baboon	Kidney	60 days
1984	Baboon	Kidney	20 days
1992	Baboon	Liver	70 days

to provide sufficient protection to allow survival of organ xenografts for periods of days to weeks. Despite the obvious advantages of administering complement inhibitors, this approach has several important limitations. First, the action of complement inhibitors is transient, whereas complement activation persists. Second, systemic inhibition of complement compromises host defense against infections. The alternative, and now standard, approach to controlling activation of complement is to express complement regulatory proteins of the recipient as the product of transgenes in the would-be source of xenografts.⁶ For example, expression of human decay-accelerating factor, CD59, and membrane cofactor protein in transgenic pigs has led to prolonged survival of organs from those pigs transplanted into nonhuman primates.^{5,7}

Xenoreactive natural antibodies

All vertebrates capable of producing antibodies have at least some natural antibodies. These antibodies are called 'natural' antibodies because they are produced without a known history of sensitization with the corresponding antigen. Natural antibodies include polyreactive antibodies, which bind to many different and disparate types of antigens, and monoreactive natural antibodies, which mainly recognize one or a few saccharides. The best-known monoreactive natural antibodies are the isohemagglutinins, which recognize the blood group A and B antigens.

Xenoreactive natural antibodies (natural antibodies that recognize the cells of foreign species) have been known for decades.⁸ Xenoreactive antibodies may be polyreactive or monoreactive. Xenoreactive polyreactive antibodies, like other polyreactive antibodies, are thought to be made by B1 B cells. Whether xenoreactive polyreactive antibodies activate complement or exert other effector functions and cause disease is uncertain. On the other hand, monoreactive xenoreactive antibodies are thought to contribute an important barrier to xenotransplantation.

The best-characterized xenoreactive antibodies are antibodies specific for Gal α 1-3Gal. Gal α 1-3Gal is produced by the action of α 1,3-galactosyl transferase on growing oligosaccharide chains. Functional α 1,3-galactosyl transferase is produced by all lower mammals and by New World monkeys. Humans, apes, and Old World monkeys do not produce a functional enzyme, and hence they make no Gal α 1-3Gal. Species such as human that make no Gal α 1-3Gal produce natural antibodies, sometimes in large amounts, specific for that sugar. Antibodies specific for Gal α 1-3Gal are monoreactive and have functional properties like antibodies specific for the A and B blood groups.

Therapeutic strategies for limiting the impact of xenoreactive antibodies have focused on: (1) immunoabsorption of antibodies; (2) inhibition

of production by immunosuppressive drugs or induction of tolerance; (3) the generation of pigs with targeted disruption of the α 1,3-galactosyl transferase; and (4) various combinations of these approaches. Depletion of xenoreactive antibodies by passage of blood through xenogeneic organs or through immunoaffinity columns has helped to demonstrate that antibodies induce much of the activation of complement in xenogeneic organ grafts and has provided some prolongation of graft survival. On the other hand, no regimen of immunosuppressive drugs yet tested has effectively inhibited production of natural antibodies (cyclosporine, leflunamide, and some other agents have helped to a varying extent to limit production of elicited antibodies). Various strategies have been devised to induce tolerance to Gal α 1-3Gal. For example, α 1,3-galactosyl transferase has been expressed in bone marrow cells of a would-be recipient, and this has apparently led to tolerance to Gal α 1-3Gal in rodents. However, no approach to induction of tolerance tested to date, including the induction of mixed hematopoietic chimerism,⁹ has yielded an enduring state of tolerance to Gal α 1-3Gal in nonhuman primates. Rather, the most effective way to deal with natural anti-Gal α 1-3Gal antibodies is the production of pigs with targeted disruption of α 1,3-galactosyl transferase.¹⁰ Organs from such pigs contain little Gal α 1-3Gal and survive for prolonged periods after transplantation into nonhuman primates.^{11,12} However, the recipients of organs from the Gal α 1-3Gal-deficient pigs were always treated with other manipulations, so it is difficult to know how much of the prolongation of survival is owed only to the absence of Gal α 1-3Gal.¹³

Natural killer cells

Xenogeneic cells are also recognized by NK cells and recognition leads to cytotoxicity *in vitro*. The mechanisms that give rise to cytotoxicity are thought to include the following: (1) failure of major histocompatibility complex (MHC) class I on the xenogeneic target to interact with killer inhibitory receptors of NK cells; (2) stimulation of Fc γ II receptors on NK cells by xenoreactive immunoglobulin G (IgG) bound to xenogeneic cells; and (3) stimulation of lectin receptors on NK cells by saccharides such as Gal α 1-3Gal on the xenogeneic target cells and activation of other cytotoxicity receptors. To what extent NK cells damage organ transplants is uncertain, as immunodeficient animals with normal NK activity can accept allografts and xenografts. However, some recent studies suggest that NK cells can induce vascular injury over a period of time, especially in xenografts. NK cells might also promote antigen presentation and, thus, elicit immune responses directed against the xenograft; these responses appear to be a main limitation of application of xenotransplantation.

Perhaps because of uncertainties about the importance of NK cells in the barrier to xenotransplantation, therapeutic strategies for inhibiting these cells have been discussed but so far have not been advanced. Among the considerations are transgenic expression of human leukocyte antigen (HLA)-E or other stimulators of inhibitory receptors.

Inflammation and coagulation as innate barriers to xenotransplantation

Besides those components generally viewed as elements of the innate immune system, phagocytes (neutrophils and macrophages), platelets, and the coagulation system can recognize and react directly with xenografts. Of course, these elements can also be recruited by innate and adaptive immune responses. Whether these cells and pathways cause greater harm by direct action on xenografts or as effectors recruited by immune reactions has not been tested. However, since inhibition of innate and elicited immunity largely prevents acute destruction of xenografts, one suspects that these elements mainly serve an accessory capacity.

ELICITED IMMUNE RESPONSES

T cells

T cells clearly recognize and destroy xenografts since cellular xenografts can survive in nude mice, but not in wild-type mice. To which extent and by what mechanism T cells recognize xenogeneic cells, however, have been matters of controversy. T-cell responses to xenogeneic cells appear to be defective when evaluated *in vitro* because cytokines and co-stimulatory molecules produced by xenogeneic antigen-presenting cells (APCs) act poorly on responding T cells. However, xenogenic APCs can present foreign MHC antigen to T cells, presumably through the use of alternative co-stimulatory pathways and cross-reactive properties of T-cell receptors. T cells may also respond *in vitro* to foreign peptides presented by self-APC. Although the nature and intensity of T-cell responses to xenotransplantation are still not completely known, the response is likely to be at least as intense as the response to allotransplantation, owing to the diverse set of antigenic peptides, an amplifying effect of humoral immunity and inflammation on cellular immune responses, and defective immune regulation.¹⁴

Elicited antibodies

Xenogeneic cells and tissues elicit powerful and diverse antibody responses. These responses, like other T-cell-dependent responses, are controlled to some extent by immunosuppressive therapy. The elicited immune response has been seen as the critical barrier to transplantation of xenogeneic organs, yet little is known about the specificity. Xenotransplantation does lead to the production of a large amount of anti-Gal α 1-3Gal antibodies, consisting of a greater fraction of IgG and exhibiting higher affinity than natural anti-Gal α 1-3Gal antibodies. However, whether these antibodies result from class switch recombination and affinity maturation in B cells producing natural Ig or the activation of novel clones is uncertain. Because production of anti-Gal α 1-3Gal antibodies or their impact on the graft might be controlled as described above, the elicited antibodies of greater importance are probably T-cell-dependent antibodies specific for other antigens.¹⁵ Unfortunately, little is

known about the specificity of the antibodies; however, these antibodies are now seen as another important barrier to successful transplantation of xenogeneic organs.

IMPACT OF IMMUNE RESPONSES ON THE XENOGRAPTS

If xenotransplantation excites nearly every facet of innate and adaptive immunity, the impact of an immune response is determined not so much by the intensity or diversity of the response as by the type of graft implanted: cell, tissue, or organ. The type of graft determines the impact of the immune response because it determines the means by which the graft receives its supply of blood, and it is the vasculature of grafts that is most vulnerable to immune-mediated injury. Figure 81.1 depicts the various responses observed following xenotransplantation of organs, tissues, and cells. Notice that organs are susceptible to various types of rejection that are not observed in cell and tissue grafts. These types of rejection focus predominantly on the vasculature of the graft.

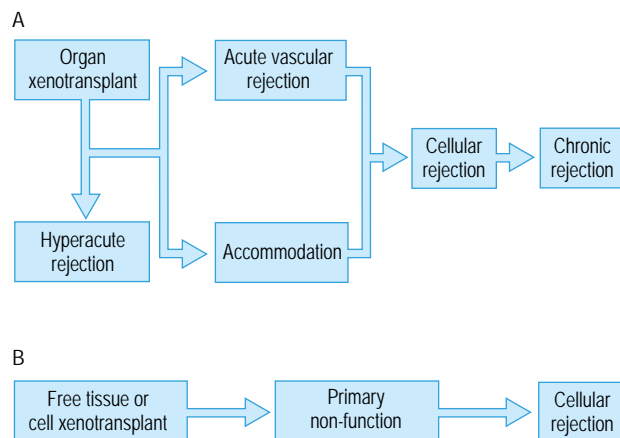

Fig. 81.1 Biological outcome of xenografts. **(A)** The outcome of organ xenotransplants. Organ xenografts are subject to vascular types of rejection, including hyperacute, acute vascular, and chronic rejection. Vascular rejection, particularly hyperacute and acute vascular rejection, are caused by the binding of antibodies and activation of complement of the recipient on xenogeneic blood vessels. Having blood vessels originating with the recipient, cell and tissue xenografts are not subject to this type of problem. Accommodation refers to acquired resistance to injury. Organ xenografts are also susceptible to cellular rejection. **(B)** The outcome of free tissue and cell xenotransplants. Cell and tissue xenografts derive their blood supply through the in-growth of blood vessels of the recipient. Since the blood vessels of these grafts are constructed from cells of the recipient, antibodies of the recipient do not generally bind to the blood vessels, and hence vascular diseases of organ grafts such as hyperacute and acute vascular rejection are not observed. Free tissue and cell xenografts are mainly subject to injury by T cells that have the ability to migrate effectively through blood vessels walls, causing primary nonfunction and cellular rejection.

HYPERACUTE REJECTION

Hyperacute rejection refers to the rejection of an organ graft within 24 hours of reperfusion; it is arguably the most severe and violent immunological reaction as it reflects the loss of graft function and destruction of the organ within a period of hours. Hyperacute rejection begins within minutes of the perfusion of a newly transplanted organ and is characterized by formation of platelet thrombi and bleeding into the graft. Organs transplanted between disparate species are especially susceptible to hyperacute rejection.

The development of hyperacute rejection depends absolutely on activation of complement in an organ graft. In some combinations of organ and recipient species, complement activation is initiated directly through the alternative pathway, owing presumably to species-specific function of factor H. This type of hyperacute rejection is especially severe and resistant to therapy, perhaps because C3b attaches simultaneously to many available sites on blood vessel walls. In clinically relevant combinations of organ and recipient (e.g., swine organs transplanted in higher primates), complement activation is mainly initiated by the classical pathway, owing the binding of xenoreactive antibodies and involvement of the alternative pathway is secondary. In this setting, the kinetics and extent of complement activation are functions of mainly antibody–antigen interaction.

Hyperacute rejection appears to reflect a loss of endothelial cell function. This loss is triggered by terminal complement complexes inserted into endothelial cell membranes. The rate of complement activation appears particularly important, as measures that slow the formation of terminal complexes, such as expression of very low levels of decay-accelerating factor and/or CD59 from the recipient species in blood vessels of the graft may prevent the disease.⁵

Hyperacute rejection can be prevented by any means that hinders activation of complement in the transplant. In pig-to-primate xenografts, such means include the depletion of xenoreactive antibodies from the circulation of the recipient, elimination by gene targeting or other means of the antigen they recognize, and the inhibition of complement reactions, such as through expression as the product of transgenes of complement regulatory proteins of the recipient species.

ACUTE VASCULAR REJECTION

If hyperacute rejection does not occur or if it is prevented, a xenografted organ is susceptible to acute vascular rejection. Acute vascular rejection emerges over a period of days to weeks and is characterized by endothelial swelling, focal ischemia, and intravascular coagulation. Acute vascular rejection, sometimes called delayed xenograft rejection or acute humoral rejection, causes destruction of a xenograft over a period of days to weeks and is now widely seen as a third major hurdle to the clinical application of organ xenotransplantation.¹⁴

Acute vascular rejection appears to be caused mainly by the action over hours to days of antibodies of the recipient directed against the graft. Besides antibodies, other factors, including macrophages, platelets, and NK cells, have been implicated in this disease. However, most transplant physicians are so persuaded about the importance of antibodies that when this type of rejection occurs in an allograft it is often referred to as ‘antibody-mediated’ rejection.

Binding of antibodies to blood vessels in a graft is thought to cause acute vascular rejection (if it does not cause hyperacute rejection) by activating endothelium. In some cases at least, activation of endothelium

depends on activation of complement and particularly the insertion of sublytic amounts of terminal complement complexes in endothelial cells. Terminal complement complexes activate the interleukin (IL)-1 α gene, leading to production of that cytokine; under some conditions, it is that cytokine that determines the subsequent fate (activation versus nonactivation) of endothelium and hence of the graft. Endothelial cell activation changes the posture of blood vessels from anti-coagulant to procoagulant and from anti-inflammatory to proinflammatory.

Several approaches have been pursued in efforts to prevent or treat acute vascular rejection. To the extent that anti-Gal α 1-3Gal antibodies trigger acute vascular rejection, the induction of immunological tolerance to Gal α 1-3Gal or the elimination of that saccharide from transplants might prevent the initiation of that process. However, neither tolerance induced by presently available means nor the elimination of Gal α 1-3Gal can prevent acute vascular rejection of xenografts.^{12, 13} In these cases, antibodies elicited against antigens other than Gal α 1-3Gal appear to incite rejection. Perhaps tolerance might be induced to a broader spectrum of antigens by transplantation of hematopoietic stem cells of the donor species into the recipient. Still another approach to preventing acute vascular rejection of xenotransplants, however, may involve the induction of accommodation.

ACCOMMODATION

Accommodation is an acquired resistance to humoral injury and acute vascular rejection of an organ graft.^{6, 16} Accommodation was first observed in the transplantation of kidneys across blood group A and B barriers when transient removal of anti-blood group antibodies from the recipients of the transplants was followed by prolonged function of the transplants after the return of the antibodies to the circulation. Accommodation has been observed in rodent models of xenotransplantation and in porcine organs transplanted into baboons where the organs express human complement regulatory proteins and the xenoreactive antibodies are temporarily depleted from the circulation of the xenograft recipient. Accommodation may exemplify a broader response in which cells exhibit reversal of noxious pathways.¹⁶ The development of accommodation may be important for the successful engraftment of xenogeneic organs because these organs contain numerous antigens that could evoke humoral immune responses.

We originally postulated that accommodation may reflect one or more of three changes following organ transplantation: (1) a change in the nature of xenoreactive antibodies; (2) a change in the antigen-impairing antibody binding; and (3) induction of cellular resistance to humoral injury.⁶ Most evidence would presently point to acquired resistance to injury as being central to accommodation. Accommodation in both rodents and pig-to-primate xenografts appears to be associated with expression of various anti-apoptotic proteins and heme oxygenase-1. In other biological systems, accommodation may require the AKT and PI3 kinase system. Which gene(s) and signaling pathways actually bring about accommodation and which are simply needed for cell survival, but not accommodation *per se*, is still uncertain.

CHRONIC REJECTION

Whether or not, and to what frequency, chronic rejection would occur in a vascularized xenograft is uncertain because of the difficulties in overcoming acute vascular rejection. Clearly, ongoing production

of anti-donor antibodies might be expected to cause chronic rejection of xenografts. If complement activation on endothelial cells or smooth-muscle cells induces proliferation of the cells and the development of chronic lesions, one might also anticipate such lesions in vascularized xenografts. Whether cell-mediated immunity would cause chronic rejection of xenografts, as it does in allografts, is unknown. On the other hand, to the extent that nonimmunologic causes of chronic rejection, such as preservation injury and infection, contribute to chronic rejection, that problem might be less in an organ xenograft.

CELLULAR REJECTION

Organ xenografts are subject to cellular rejection more or less like what is observed in organ allografts. The rejection of organ xenografts, like the rejection of organ allografts, presumably targets foreign major histocompatibility antigens. However, unlike allografts, practically all of the non-MHC proteins in xenografts are immunogenic. Above we discussed the several distinct aspects of this response. Here it can be said that cellular immune responses to xenografts are not necessarily limiting and are apparently subject to control by the same therapeutic agents as cellular immune responses to allografts. Some evidence does suggest that the response to xenografts may be especially susceptible to therapeutics aimed at CD4 T cells.

COAGULATION AND THROMBOSIS IN XENOTRANSPLANTATION

Organ xenografts are plagued by coagulation and thrombosis. Thrombosis occurs in acute vascular rejection and may occur independently of rejection, owing to defective control of thrombin generation and hemostasis on xenogeneic endothelium. As two potential mechanisms for the latter, porcine von Willebrand factor spontaneously aggregates human platelets and porcine thrombin might interact inefficiently with human thrombomodulin.

CLINICAL RELEVANCE

Xenografts could provide an abundant source of organs, tissues, and cells for transplantation

Xenografts might evade recurrence of viral or immunologic disease

Some day, human cells, tissue, or organs might actually be grown in animals for transfer later into humans

Xenografts provide excellent models for elucidating mechanisms of vascular disease and accommodation and for testing the efficacy of modifiers of innate and adaptive immune responses

REJECTION OF CELL AND TISSUE XENOGRAFTS

Although cell and tissue xenografts incite humoral immune responses, unlike organ xenografts, cell and tissue xenografts are not subject to devastating vascular rejection. Cell and tissue xenografts are not susceptible to vascular rejection because the blood vessels of those grafts grow in from the recipient and thus consist of cells to which the recipient is tolerant. Consistent with this concept, cell and tissue xenografts appear to be undisturbed by high levels of antibodies in the recipient specific for the grafted cells. On the other hand, cell and tissue xenografts are susceptible, perhaps quite susceptible, to primary nonfunction and to cellular rejection (Fig. 81.1B).¹⁴ Both primary nonfunction and cellular rejection may be mediated by T cells; however, NK cells might also have importance, for reasons discussed above.

INFECTIOUS DISEASE AS A BARRIER TO XENOTRANSPLANTATION

If the immunological response of the recipient to a xenograft poses the most difficult biological barrier to xenotransplantation, the potential transfer of infectious organisms from the graft to the recipient may imperil the health of the community. While many microbial organisms infect one or only a few related species, some, such as influenza and severe acute respiratory syndrome (SARS), can pass between disparate species and then more broadly, with potentially devastating consequences.

In principle, the transfer of infections from a graft to the recipient should be less of a problem in xenotransplantation than in allotransplantation. After all, one can characterize infectious agents present in an animal source and potentially eliminate those agents by breeding and special housing conditions. Further, because the microbial organisms present in a source of xenografts are potentially known, the benefits of transplantation can be weighed against the risks of infection. Further, if the source of xenografts is a species such as the pig, which has been in close contact with humans for centuries, then the risks of zoonotic disease are known.

One exception to this sanguine view of trans-species infection in xenotransplantation is the possibility that pigs might have an endogenous retrovirus that could pass into the human, cause disease, and eventuate human-to-human infections. Endogenous retroviruses are broadly represented in the species (and indeed they are transmitted vertically) and hence cannot be easily eliminated by breeding. The porcine endogenous retrovirus (PERV) present in various forms in all strains of pigs is such an agent. PERV from porcine cell lines and from activated porcine cells can infect human cells in culture. However, extensive surveys of humans who received experimental xenografts of various types or who were temporarily exposed to porcine organs and blood products have failed to provide any evidence that PERV can pass from pig organs or tissues to human cells *in vivo*.¹⁷ However, the analysis of chimeric pigs harboring human hematopoietic cells revealed PERV could pass from swine into human cells if the swine and human cells fuse spontaneously.¹⁸ Indeed, cell fusion provides a potential mechanism for retroviral transfer and recombination between species (Fig. 81.2). Passage of PERV into

Fig. 81.2 Transmission of virus by cell fusion. Cell fusion may facilitate transmission of viruses and contribute to emergence of novel viruses. Fusion of a cell infected with a virus with an uninfected cell allows the virus (dark black bar) from infected cell (blue) to enter the genome of uninfected cell (red) by nuclear fusion. When the virus is activated and buds from the 'infected' cell, it acquires surface proteins from the uninfected fusion partner (red) and is thus capable of infecting other similar cells by viral entry. When nuclear fusion allows a virus of one species to enter the genome of another species, mutation and translocation of chromosomes may facilitate the generation of novel viruses. (Adapted from Ogle BM, Cascalho M, Platt JL. Biological implications of cell fusion. *Nat Rev Mol Cell Biol* 2005; 6: 567–575.)

human cells by cell fusion would have been missed in previous surveys because the conclusion that infection had not occurred depended on quantitative or semiquantitative polymerase chain reaction (PCR) or assay of swine–human chimerism, and when cells fuse, some genes, potentially those assayed in the PCR reaction, are lost. Thus, the question of PERV transfer into humans remains to be answered.

One other implication of xenotransplantation for host defense pertains to the control of intracellular infections by cell-mediated immunity. Since cell-mediated immunity depends to a certain extent on T-cell responses that are more or less MHC-restricted, the recipient might not control viruses and other intracellular organisms that invade the graft. Thus, the factors, such as MHC restriction, incompatibility of cytokines and cell adhesion molecules that impair T-cell responses to xenogeneic cells, discussed above, might have the greatest impact on host defense. At present, this limitation is theoretical; however, some who conduct experimental transplants have noticed that viruses such as CMV may engender more severe or more complicated problems in the recipients of xenografts than in the recipients of allografts.

CONCLUDING REMARKS

The immunology of xenotransplantation is a subject of medical interest. The application of transplantation for the treatment of human disease is significantly constrained by a shortage of human organs, and overcoming the immunological barriers to xenotransplantation would surely solve that problem. Whether xenotransplantation is applied for this purpose and to what extent will also depend on advances made in other technologies.^{3, 19} One might imagine that cloning and new applications for stem cells could efface or even eliminate the demand for xenotransplantation. However, interest in xenotransplantation will likely persist, despite the failure to overcome

the immunological barriers and the advance of alternative technologies. Such interest should stem from xenotransplantation as an experimental model. Thus, today, one can find no better or more rigorous model than a xenograft for testing the efficacy of therapeutics for the complement or coagulation systems. Furthermore, xenografts have provided very powerful models for elucidating the mechanism of complement-mediated injury, the pathophysiology of endothelial cell activation, and the biological phenomenon of accommodation.⁶ Finally, xenografts have begun to teach unexpected lessons, such as the developmental implications of cell fusion and mechanisms of transfer of viruses between species.¹⁸

Hematopoietic stem cell transplantation for malignant diseases

Scott Rowley, Thea M. Friedman, Robert Korngold

82

Hematopoietic stem cell transplantation (HSCT) is currently the therapy of choice for most hematological malignancies, including all forms of leukemia, lymphoma, and multiple myeloma that are nonresponsive to first-line chemotherapeutics, as well as the clonal but nonmalignant myelodysplastic and myeloproliferative disorders. Autologous HSCT is commonly used as salvage therapy for patients with malignancies sensitive to chemo-/radiotherapy in a dose-responsive manner. These patients receive very dose-intensive cytoreductive regimens designed to eliminate all tumor cells, but in so doing also destroy the stem cell elements needed to populate the hematopoietic compartment. Infusion of previously collected HSC will rescue the patient from the marrow-ablative effects of this treatment. On the other hand, allogeneic HSCT, which will also reconstitute bone marrow function after dose-intensive chemo-/radiotherapy, is now also used to provide an immunotherapeutic approach with the intention of allowing donor T cells to attack residual tumor cells that remain after the conditioning regimen, reducing the risk of later disease relapse. Thus, allogeneic HSCT does not require the administration of dose-intensive regimens to achieve complete tumor cell kill, and lower-intensity nonmyeloablative regimens may be used to 'condition' the host for transplantation.

Autologous (including syngeneic [identical twin]) HSCT is justified by the dose sensitivity of most hematological malignancies. Although there is some evidence that faster immunological recovery after autologous HSCT predicts a lower risk of relapse, possibly opening an area of research in graft modification to enhance such recovery, treatment of the disease is a result of the chemotherapy administered, with infusion of cells only required to hasten hematological recovery. The primary complications of autologous HSCT result from the administration of the dose-intensive pre-transplant regimen and include a period of marrow hypoplasia, possibly requiring blood transfusions and antibiotics. Nonhematological toxicities, including mucositis resulting in inanition, and diarrhea, and damage to other organs such as lung, liver, and kidney, limit the amount of chemotherapy that can be administered. Relapse of disease, however, is the primary cause of death after autologous HSCT, and improvements in the outcome will probably require new strategies to induce effective immune responsiveness to the residual disease.

THERAPEUTIC PRINCIPLES

AUTOLOGOUS VERSUS ALLOGENEIC HSCT

Autologous transplantation

- >> Based on chemo-/radiotherapy dose-sensitivity of primary disease
- >> Requires collection and storage of adequate HSC, preferably before extensive alkylating agent or purine analog therapy
- >> Lower risk of graft failure (no immunologic rejection)
- >> No routine post-transplant immunosuppression
- >> Minimal or no risk of GvHD
- >> Quicker post-transplant immune reconstitution
- >> Minimal or no GvL effect
- >> Variable risk of tumor cell contamination in donor infusate
- >> Not useful for diseases in which normal HSC cannot be collected (e.g., chronic myelogenous leukemia, myelodysplasia)

Allogeneic transplantation

- >> Rescues bone marrow function after dose-intensive therapy
- >> Effective with reduced-intensity conditioning regimens
- >> Achieves a GvL effect in many malignancies
- >> Risk of GvHD that may be uncontrollable
- >> Higher risk of transplant-related complications that may offset the benefit of the GvL effect
- >> Risk of immunological graft rejection
- >> Slow post-transplant immune reconstitution
- >> No risk of tumor cell contamination
- >> Risk of disease transmission (viral infections, cancer) from donor

Allogeneic HSCT has a much lower relapse risk as a result of an immunological graft-versus-leukemia (GvL) effect, but a much higher risk of transplant-related mortality (TRM). The principal complication of allogeneic HSCT is still graft-versus-host disease (GvHD). The overall incidence of moderate to severe acute GvHD (aGvHD) is between 35% and 80% for all patients receiving an HLA-matched related or unrelated donor stem cell inoculum, and aGvHD is a primary cause of death in 10–20% of these HSCT patients. Chronic GvHD (cGvHD), which develops more than 100 days after allogeneic HSCT, is another form of this immunological complication and occurs in over 25% of all recipients, may involve aspects of regulatory T-cell dysfunction and autoimmune-like responses, and may require years of therapy before tolerance is achieved and immunosuppressive medications can be discontinued. Other significant complications to both autologous and allogeneic HSCT relate to problems of adequate reconstitution of the patient's immune system, the concomitant risk of opportunistic infections, and the possibility of malignant relapse. Despite the apparent risks associated with allogeneic HSCT, this treatment holds great promise as a curative therapy for several tumor types, particularly in light of many novel strategies to boost immune responses in these transplanted patients via adoptive immunotherapy or with different vaccine approaches. In addition, efforts have been made in recent years to make HSCT less toxic to the patient with nonmyeloablative conditioning regimens, which have allowed the availability of transplantation as a treatment option to a much broader patient population. These intriguing developments have also opened up the possibility of applying HSCT to not only hematological malignancies, but to solid tumors as well.

■ IMMUNE MECHANISMS RELATED TO ALLOGENEIC HSCT ■

HISTOCOMPATIBILITY

The HLA major histocompatibility complex (MHC) (Chapter 5) is the primary consideration in selecting a donor for allogeneic HSCT, as its loci contribute significantly to host-versus-graft (HvG, leading to immunological rejection of donor HSC) and to graft-versus-host (GvH, leading to GvHD and GvL) reactions. HLA antigens are classified as class I (HLA-A, B, C) and class II (HLA-DR, DQ, DP) molecules, and typing of donors and patients can be performed using low- or high-resolution techniques. The low-resolution serological techniques can determine a phenotypic mismatch (e.g., A02 vs A03), whereas high-resolution molecular techniques can identify allelic genotypic differences (e.g., A0201 vs A0202). The risk of GvHD and transplant-related mortality increases with the number of HLA mismatches, and ideally, genotypically matched unrelated donors are sought for patients lacking an HLA-identical sibling. Disparity at HLA-A, -B, -C, and DRB1 alleles is a definite risk factor for GvHD, whereas single HLA-DQ or -DP mismatches do not seem to have the same effect.¹

In addition to HLA, minor histocompatibility antigens (miHA), expressed on host cells, can also be a problem in causing GvHD. These antigens are derived from polymorphic sites in normal proteins between individuals that are constantly processed by proteasome activity and presented on the cell surface by MHC molecules, and can thus be recognized by T cells from an HLA-matched donor. As a result, there may be hundreds of these miHA available between a donor and an HSCT

recipient, and some of these are capable of causing GvHD, partially depending on the tissues in which they are expressed. Unfortunately, only a few miHA have been identified, and it is currently very difficult to screen for mismatches. As a result, miHA are largely responsible for the remaining incidence of GvHD (30–50%), even if there is a complete genotypic HLA match. In contrast, mismatching for either red cell antigens, including ABO, Rh, and other hemolytic antigens, or for killer immunoglobulin-like receptor (KIR) ligands, does not seem to affect the development of GvHD.²

GvHD

GvHD is caused by mature donor T cells contaminating the HSC inoculum, which can recognize HLA or miHA differences expressed by host antigen-presenting cells and tissues (Fig. 82.1).³ Cytokines released from host cells after a patient has received dose-intense tumor cytoreductive chemo-/radiotherapy conditioning create an inflammatory environment that enables the generation of a response of infused donor T cells against host antigens. This initiates a cascade of T-cell activation events that results in proliferation, the release of additional inflammatory cytokines, and the generation of effector T cells that can infiltrate target tissue, particularly the lymphoid system, intestinal tract, skin, and liver, and mediate destruction of host cells in those organs. Both CD4 and CD8 T cells can be involved in GvHD, depending on the specific class I or class II HLA or miHA disparities involved.

The simplest way to avoid the development of GvHD is to deplete the donor HSC inoculum of T cells, bringing their constituency for infusion down below 10^5 cells/kg. Since the 1990s this approach has succeeded in significantly diminishing the incidence of GvHD, but other complications related to the ensuing delay in immune reconstitution of recipients, an increased risk of relapse from loss of the GvL effect, and a higher rate of engraftment failure (also due to loss of the GvH effect) have resulted in very little improvement in long-term survival after T cell-depleted HSCT, compared to transplantation with T-replete products.⁴ The conundrum in the HSCT field is that the same alloreactive donor T cells that are responsible for GvHD can also mediate an effective GvL response, although there may also be additional donor leukemia-specific T cells. Thus, the overriding goal is to be able to manipulate the donor HSC inoculum in such a way as to avoid GvHD, but to still be able to mediate a GvL effect.

CLINICAL ASPECTS OF aGvHD

Usually developing within the first 100 days, aGvHD is a clinical diagnosis with laboratory confirmation; the most common presenting manifestations include skin rash; nausea, anorexia, and diarrhea; and jaundice, depending upon the target organ(s) most affected.⁵ The severity of aGvHD is graded and staged according to the extent of involvement of these organ systems (Tables 82.1 and 82.2). In addition to the increased risks of developing aGvHD related to the extent of donor HLA disparity, additional factors include the increasing age of either the donor or the recipient, gender disparity, and infusion of T cell-replete HSC products. Conditioning with reduced-intensity regimens that have lower regimen-related toxicities to nonhematological tissues also results in a lower risk of aGvHD, and may also delay the onset of its initial manifestation. Inflammation by gut bacteria (gnotobiosis) appears to have a weak effect on the development of aGvHD in related donor transplantation, and is

Fig. 82.1 Development of GvHD. Cytoablative preconditioning treatment of patients with hematological malignancies using whole-body irradiation or chemotherapeutic drugs causes damage to epithelium in the skin and gastrointestinal tract and activates the release of inflammatory cytokines by dendritic cells (DC) and macrophages (Mφ) in those tissues. These cytokines include tumor necrosis factor-α (TNF-α) and interleukin (IL)-1, which upregulate adhesion molecules and chemokine release in the vascular endothelium of the tissues. Activated DC also migrate to the lymphoid system, where they can present recipient histocompatibility antigens to infused donor T cells that are in the hematopoietic stem cell graft. The DC release IL-12 which helps to activate CD4 and CD8 T cells, as well as natural killer (NK) cells. These responding cells proliferate and produce additional inflammatory cytokines, including interferon-γ (IFN-γ), TNF-α and IL-2. Mφ are activated by both IFN-γ and lipopolysaccharide (LPS) produced by bacteria found in the intestinal tract, and these cells then produce high levels of more TNF-α. TNF-α has many properties, including direct induction of apoptosis of cells in the tissues of target organs of GvHD, but it also helps effector T cells to home to and enter tissue sites through the vascular endothelium. Effector T cells specific for host histocompatibility antigens then become reactivated and perform their effector functions, including release of inflammatory and cytolytic cytokines and direct killing of recipient-type cells in the lymphoid compartment and in the skin, gut, and liver.

probably related to the production of the highly inflammatory agent lipopolysaccharide. Gut decontamination will decrease the risk of developing aGvHD, although at the cost of other complications, including increased colonization with antibiotic-resistant organisms.⁶

Pharmacological agents (Chapter 90) are the mainstay of prophylaxis for aGvHD. Most patients receive a two-drug combination of a calcineurin inhibitor (tacrolimus or cyclosporine) along with an anti-metabolite such as methotrexate or mycophenylate mofetil (MMF). Methotrexate is associated with delayed engraftment, mucositis, idiopathic pneumonia

KEY CONCEPTS

GRAFT-VERSUS-HOST DISEASE (GvHD)

- >> Caused by donor/recipient differences in:
 - Major histocompatibility complex (MHC) molecules
 - Minor histocompatibility antigens (miHA)
- >> Mediated by mature donor CD4 and/or CD8 T cells
- >> Requires inflammatory cytokines
- >> Primary target organs include lymphoid system, skin, gastrointestinal tract, and liver
- >> Acute and chronic forms

syndrome, and other transplant-related complications, prompting the development of other combination regimens, such as a calcineurin inhibitor in combination with sirolimus or MMF, or reduced doses of methotrexate. The addition of anti-thymocyte globulin (ATG) to the conditioning regimen lowers the incidence of both GvH and HvG reactions without greatly increasing the toxicity of the conditioning regimen, because of the persistence of this agent for several days after HSC infusion.⁷ However, patients treated with ATG may face a higher risk of infectious complications, including EBV-associated post-transplant lymphoproliferative disorder, as a result of the greater immunosuppression achieved.

Glucocorticoids (Chapter 87) remain the standard approach to initial systemic management of clinically significant aGvHD. Patients who fail to respond to initial therapy have a poor prognosis, as additional agents added for control increase the risk of opportunistic infections and other complications. The use of higher doses of corticosteroids, or the addition of ATG, for example, in the initial treatment of aGvHD have not improved the outcome and should be reserved for patients who are refractory to initial therapy.^{8,9} The infusion of regulatory cells such as mesenchymal stem cells is an interesting approach to the treatment of aGvHD, and studies of this therapeutic approach are ongoing.¹⁰ A number of drugs, including ATG, pentastatin, switching to tacrolimus from cyclosporine, and newer monoclonal antibodies, have shown limited activity in the salvage treatment of patients with steroid-refractory aGvHD.¹¹ Extracorporeal exposure of peripheral blood mononuclear cells (PBMC) to the photosensitizing agent 8-methoxypsoralen and UV-A radiation (photopheresis) has been shown to be effective in the treatment of selected diseases mediated by T cells, including both aGvHD and cGvHD, and is a novel approach to the treatment of patients with steroid-refractory GvHD, although the mechanism of this effect remains to be elucidated.¹²

A form of aGvHD can also occur after autologous HSCT, probably as a manifestation of immune system dysregulation during reconstitution of the immune system following dose-intensive therapy.¹³ Autologous aGvHD is usually a very limited complication and easily managed with a course of corticosteroids, in contrast to the more extensive and difficult-to-manage aGvHD that occurs after allogeneic HSCT. In contrast to allogeneic HSCT, cGvHD has not been reported to occur after autologous transplantation.

Table 82.1 Clinical grading of acute GvHD (Adapted from Glucksberg H, Storb R, Fefer A, et al. Clinical manifestations of graft-versus-host disease in human recipients of marrow from HLA-matched sibling donors. Transplantation 1974; 18: 295–304)

Overall grade	Skin stage	Liver stage	Gut stage	Functional impairment stage
0 (none)	0	0	0	0
1 (mild)	1–2	0	0	0
2 (moderate)	1–3	1	1	1
3 (severe)	2–3	2–3	2–3	2
4 (life-threatening)	1–4	1–4	1–4	3

Table 82.2 Clinical staging of acute GvHD (Adapted from Glucksberg H, Storb R, Fefer A, et al. Clinical manifestations of graft-versus-host disease in human recipients of marrow from HLA-matched sibling donors. Transplantation 1974; 18: 295–304)

Stage	Skin	Liver	Gut
1	Maculopapular rash <25% BSA	Bilirubin 2–3 mg/dL	Diarrhea 500–1000 ml/day, or Persistent nausea
2	Maculopapular rash 25–50% BSA	Bilirubin 3–6 mg/dL	Diarrhea 1000–1500 ml/day
3	Generalized erythroderma	Bilirubin 6–15 mg/dL	Diarrhea >1500 ml/day
4	Desquamation and bullae formation	Bilirubin >15 mg/dL	Pain ± ileus

CLINICAL ASPECTS OF cGvHD

cGvHD is the leading cause of late TRM among recipients of allogeneic HSCT, and resembles autoimmune disorders such as scleroderma, Sjögren's syndrome, and primary biliary cirrhosis. As with aGvHD, diagnosis is based on clinical observations with secondary laboratory confirmation (Table 82.3).¹⁴ A falling performance status, progressive weight loss, or recurrent infections are usually signs of clinical extensive cGvHD. About 50% of long-term survivors will develop cGvHD at a median of 9 months, and patients must be monitored closely for at least 2 years after transplantation so that appropriate treatment can be started before extensive target end-organ damage ensues.

Factors predictive for the development of cGvHD again include the degree of HLA disparity, but also include the source of HSC in that peripheral blood stem cell (PBSC) transplantation conveys a higher risk than marrow or cord blood transplantation. Patients who develop cGvHD have a higher risk of TRM but a lower risk of relapse as a result of the immunological GvL effect.¹⁵ T-cell depletion may decrease the risk of cGvHD, although this has not been demonstrated in all studies.¹⁶ Most patients require at least two drugs for treatment of cGvHD, the standard initial treatment again being glucocorticoids and a calcineurin

inhibitor. About half of patients with cGvHD do not achieve complete remission (CR) with first-line therapy, although the manifold signs and symptoms of cGvHD complicate the definition of response to treatment.¹⁷ There are no clear recommendations regarding second-line treatments, and a variety of pharmacologic and immunologic techniques have been used. Re-transplantation is ineffective, but a single-center report of low-dose thoracoabdominal irradiation described an 82% response rate, with the best responses observed in patients with fasciitis or oral involvement.¹⁸ Photopheresis has an overall response rate of 50–60%, with many cGvHD patients achieving complete control of this complication.¹⁹

GvL RESPONSES

An inverse correlation has been observed in allogeneic HSCT patients between the incidence and severity of GvHD and the relapse rate of chronic myeloid leukemia (CML), and to a lesser extent acute myeloid leukemia (AML).²⁰ This relationship has not been so clear in other forms of hematological malignancy, such as acute lymphocytic leukemia (ALL) or multiple myeloma. Relapses after HSCT are thought to occur because of the survival of a few leukemia lineage stem cells in the bone

Table 82.3 Staging of chronic GvHD¹⁴

Target organ	Score 0	Score 1	Score 2	Score 3
Performance score	KPS 100%	KPS 80–90%	KPS 60–70%	KPS <60%
Skin	No symptoms	<18% BSA	19–50% or sclerotic, still able to pinch	>50% or 'Hidebound'
Mouth	No symptoms	Mild symptoms, no limitations	Moderate symptoms, decreased oral intake	Severe symptoms with major decrease in intake
Eyes	No symptoms	Mild dry eyes	Moderate dry eyes, drops >3x/day	Severe dry eyes affecting daily activities
GI tract	No symptoms	Symptoms without weight loss	Symptoms with moderate weight loss (5–15%)	Symptoms with weight loss >15%
Liver	Normal LFTs	LFTs elevated <2 × upper limits of normal	LFTs elevated 2–5 × upper limits of normal	LFTs elevated >5 × upper limits of normal
Lungs	No symptoms	Mild symptoms FEV 60–79%	Moderate symptoms FEV 40–59%	Severe symptoms FEV <40%
Joints and fascia	No symptoms	Mild tightness not affecting daily activities	Tightness affecting daily activities	Contractures with significant loss of range of motion
Female genital tract	No symptoms	Symptomatic with middle signs on examination	Symptomatic with dyspareunia	Symptomatic with strictures

National Institutes of Health consensus development project on criteria for clinical trials in chronic graft-versus-host disease: I. Diagnosis and staging working group report. Biol Blood Marrow Transplant 2005; 11: 945–956. Mild cGvHD involves only 1 or 2 organs (except lung). Moderate involves at least one organ with clinically significant but not major disability (maximum score of 2, lung score of 1 or 2). Severe cGvHD indicates major disability (a score of 3 for any organ).

marrow after administration of the pre-transplant conditioning regimen, and their outgrowth several months after HSCT. The ability to mediate an effective GvL response probably depends on several factors, including the presentation of appropriate antigens by MHC class I and/or class II molecules on the tumor cells themselves, that can be recognized by effector CD4 or CD8 T cells; the lack of strong regulatory T-cell (Treg) activity that may be induced by cytokines from the tumor cells; tumor cell susceptibility to lysis by effector T cells (e.g., the level of Bcl-2 expression and the ability to resist apoptosis induction); ability of T cells to home to sites of tumor growth; and the direct effect of immunosuppressive cytokines, such as TGF- β , produced by the tumor cells. Many types of tumor cell downregulate expression of MHC on their surface, and perhaps CML and AML are most susceptible to GvL responses because the myeloid lineage is adapted for antigen presentation and high MHC expression.

A number of novel immunotherapeutic approaches are being developed to overcome many of these obstacles and enhance GvL responses, keeping in mind that GvHD must also be avoided or minimized to improve outcomes (Fig. 82.2). One example is the use of delayed donor lymphocyte infusions (DLI), which are administered months after HSCT, at a time when the recipient cytokine environment is less conducive to GvHD induction.

PBMC components, collected from donors with or without granulocyte colony-stimulating factor (G-CSF) treatment, are also effective as

Fig. 82.2 GvHD and GvL responses. Donor T-cell responses to recipient antigens can cause GvHD, but can also target residual leukemia cells. T cells causing GvHD may recognize ubiquitous or tissue-restricted antigens (either MHC or miHA). Many of these recipient antigens may also be expressed by the leukemia cells and allows for a GvL response. Additional leukemia-specific (e.g., bcr-abl, proteinase 3, or c-akt) or tissue-restricted antigens (some miHA, as those expressed only by certain lineages of hematological cells) may be dominantly expressed by the tumor cells and can be targeted by donor T cells without causing GvHD.

CLINICAL PEARLS

MAJOR ISSUES RELATED TO SUCCESS OF ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION

- >> Graft-versus-host disease (GvHD)
- >> Graft-versus-leukemia (GvL) responses
- >> Immune reconstitution
- >> Infections

DLI immunotherapy for patients with progressive disease following allogeneic HSCT. Patients with low-grade lymphoid malignancies, such as CLL, indolent non-Hodgkin lymphoma (NHL), mantle cell NHL, and CML have the highest likelihood of response. One survey of 25 transplant programs identified 140 patients who had received DLI and reported a complete response rate of 60% in those with CML. Response rates were higher in patients with cytogenetic and chronic-phase relapse (75.7%) than in those with accelerated-phase (33.3%) or blastic-phase (16.7%) relapse, and almost 90% of these patients remained in remission 2 years after treatment.²¹ Complete remission rates in AML and ALL patients who had not received pre-DLI chemotherapy were 15.4% and 18.2%, respectively. Complications of DLI included aGvHD (60%), cGvHD (60.7%), and pancytopenia (18.6%), particularly in CML treated patients. The development of GvHD after DLI correlated highly with disease response ($P < 0.00001$).

The number of lymphocytes infused is important in achieving the DLI effect, and it may be possible to induce GvL using doses of lymphocytes that are less likely to result in GvHD.²² However, a clear distinction between the cells responsible for inducing GvL and those causing GvHD has not been found, although several novel approaches, including the use of T-cell repertoire analysis, are in the developmental stage.²³ The delay in response between DLI and the development of a GvL effect suggests that only a minority of the cells infused recognize the tumor cell antigens and must undergo *in vivo* expansion before a therapeutic effect is achieved. Thus, it may also be possible to develop leukemia-specific cytotoxic T cells in the laboratory, reducing the delay in effect and possibly increasing the GvL potential in the more rapidly proliferative acute leukemias.²⁴ Donor immunity can be transferred, at least transiently, to the host, as demonstrated by delayed-type transfusion reactions to host red blood cells, mediated by donor lymphocytes transfused along with the HSC product. Adoptive transfer of donor immunity against specific targets can be achieved, but its persistence requires immunization of both the donor and the recipient. A clinical utility for such manipulation of the immune system has not yet been demonstrated, but is clearly of interest as a technique to prevent post-transplant infections and/or disease relapse.

ADJUVANT THERAPY WITH AUTOLOGOUS HSCT

The incidence of relapse after high-dose therapy leads to the conclusion that high-dose therapy with autologous HSCT, although well tolerated and able to prolong life, should be viewed as a platform for other approaches that may be effective in eliminating the minimal residual

disease (MRD) of patients destined to relapse. Additional or yet higher-dose chemo-/radiotherapy, unless targeted directly to the tumor, increases the risk of nonhematopoietic toxicity and TRM from causes other than relapse. Immunotherapies are of interest in this regard, and include administration of post-transplant cytokines; the addition of tumor-specific antibodies, used before and/or after HSCT as an *in vivo* purge; and the development of tumor-specific vaccines, such as with tumor-antigen pulsed dendritic cells (DC).²⁵ Preliminary data on DC-derived cellular vaccines illustrate the potential promise of cell-based therapy for patients with multiple myeloma and other types of cancer, such as renal cell carcinoma, pancreatic or prostate cancer, and melanoma. The immunoglobulin idiotype found in most patients with multiple myeloma and indolent NHL, which is unique to the malignant clone, serves as a unique tumor-associated antigen for DC pulsing. The treatment appeared to be well tolerated by patients with minor and transient side effects, if any at all.²⁶ After vaccination, idiotype-specific responses were observed, characterized by T-cell proliferative responses with cytokine release and the production of anti-idiotypic antibodies, although again, a clinical benefit remains elusive.

CLINICAL HSCT

SOURCES OF HSC

Bone marrow, peripheral blood (PBSC), or umbilical cord blood (UCB) are all appropriate sources of HSC for autologous, syngeneic, or allogeneic transplantation, the primary differences being the quantities of HSC in each product and the quantities and functions of other blood cells that may influence the immunological outcomes of transplantation. PBSC have virtually replaced bone marrow as the HSC source for autologous HSCT and are widely used for allogeneic HSCT. Transplantation of PBSC (rather than bone marrow) achieves more rapid hematological recovery in both autologous and allogeneic transplant settings, resulting in lower complication rates and lower treatment costs. PBSC appear to improve overall and disease-free survivals for allogeneic recipients with advanced hematological malignancies, although at the cost of a significant risk of extensive cGvHD.²⁷ In regard to immunological reconstitution, allogeneic PBSC transplantation results in a decreased ratio of Th1/Th2 CD4 cells, which may adversely affect the ability to counteract infections and may favor the development of cGvHD.²⁸ It is also interesting to note that PBSC tend to contain about 10 times more T cells than bone marrow product, yet those T cells are less functional, possibly because of inhibition by granulocytes activated by the G-CSF used for HSC mobilization.²⁹

UCB is a rich source of HSC, with the major limitation for clinical use being the small quantity of cells collected, resulting in slower recovery of hematological function and increased risk of failure of sustained engraftment. A very significant advantage, however, is the lower risk of GvHD because of the relative immaturity of the donor immune system, allowing for the use of HLA-mismatched units without a prohibitory increase in transplant complications.³⁰ In general, as with other sources of HSC, outcomes of UCB transplantation reflect patient characteristics, with lower survival probabilities for patients with advanced diseases or poorer performance status at the time of transplantation. A number of investigators have proposed combining units of UCB in order to increase the cell dose infused into the patient, possibly increasing the speed of hematological recovery.³¹ *Ex vivo* expansion of one or more UCB units is also

THERAPEUTIC PRINCIPLES

SELECTION OF HSC PRODUCTS FOR TRANSPLANTATION

>> Bone marrow

Adequate quantities of cells can be obtained from most patients and donors
Cytokine administration before harvesting may increase the quantities of HSC collected and the number and function of accessory cells affecting transplant outcomes
Lower risk of chronic GvHD than PBSC

>> PBSC

Faster hematological recovery than bone marrow or cord blood
Better survival after related-donor HSCT for patients with advanced malignancy
Lower tumor cell contamination than bone marrow collected from autologous patients
Cytokine administration before harvesting may increase the quantities of HSC collected and the number and function of accessory cells affecting transplant outcomes

>> Umbilical cord blood (UCB)

Relative immaturity of donor immune system permits multiple-antigen mismatched transplantation
Transplant outcomes similar to mismatched unrelated bone marrow transplantation
Slower hematological recovery than either PBSC or bone marrow
Availability of stored units facilitates transplantation for patients with immediate need

being studied as a mechanism to achieve higher cell doses and more rapid hematological recovery.³²

Cell dose is an important predictor of outcome for both autologous and allogeneic HSCT, and HSC comprise a very small portion (generally <1%) of the marrow, PBSC, or UCB product. It is now recognized that successful establishment of donor cell chimerism after allogeneic transplantation is a complex interplay of pre- and post-transplant suppression of the host immune system, the dose of HSC and accessory cells (including donor lymphocytes) contained in the graft, and donor HLA compatibility (Fig. 82.3). HLA-mismatching, T-cell depletion, and less intensive conditioning regimens all raise the risk of graft failure. Autologous HSCT does not present a likely risk of engraftment failure if the viability of the HSC is maintained during processing and storage, and adequate quantities of cells are infused. Instead, the speed of hematological recovery is related to the quantity of HSC re-infused, with most studies demonstrating an exponential relationship between cell dose and rate of engraftment.³³ For marrow-ablative regimens, increasingly higher CD34⁺ cell (a surrogate marker of immature HSC) doses result in a greater likelihood of rapid recovery of peripheral blood counts.³⁴

Influence of graft, donor, and host factors on allogeneic HSC engraftment

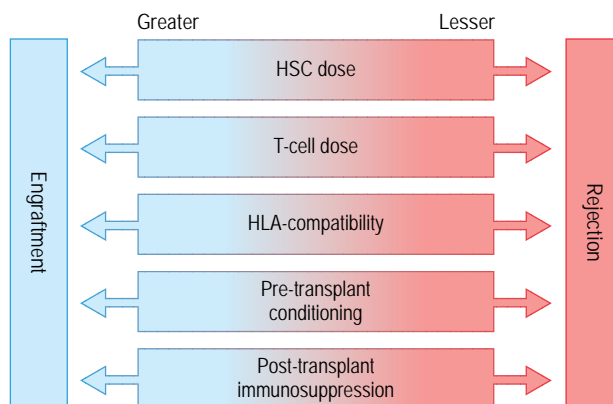

Fig. 82.3 Effect of donor and graft characteristics on allogeneic HSCT. Hematological engraftment requires that the HvG reaction be overwhelmed, by the administration of a more intensive conditioning regimen before transplantation, the use of more immunosuppressive medications after transplantation, closer matching of donor with host, or by the infusion of donor lymphocytes that can affect the development of GvHD.

Autologous recipients who receive a dose of CD34⁺ cells above an undefined threshold will engraft. At lower doses of CD34⁺ cells there is considerable heterogeneity in engraftment speed, especially for platelet recovery, with some patients experiencing quick engraftment despite low doses of PBSC.³⁴ Recipients of products containing $2\text{--}3 \times 10^6$ CD34⁺ cells/kg recipient weight have more consistently rapid granulocyte and platelet engraftment. Importantly, the duration of aplasia predicts the incidence of TRM after autologous or allogeneic HSCT.³⁵

Similarly, the cell dose is a predictor of outcome for patients undergoing allogeneic HSCT.³⁶ In one study the actuarial 5-year TRM, overall survival, and disease-free survival significantly favored patients receiving grafts with higher cell doses ($>5 \times 10^8$ nucleated cells/kg). The cell dose effect was more pronounced in patients over 30 years of age, those with advanced disease, those with a diagnosis of CML, and those with alternative donors (other than HLA-compatible siblings). A similar study reported an association between CD34⁺ cell dose and the outcome of allogeneic HSCT with either marrow or PBSC.³⁷

HSC products are not uniform in characteristics and the relative contributions of CD34⁺ cell dose and the doses of accessory cells, including CD4, CD8, and NK-cell populations, on the outcome of transplantation remain unsettled. Whether or not this is clinically significant, the cell product collected can be modified by the cytokines and chemokines, used singly or in combination, to mobilize HSC into the peripheral blood for collection or to affect the characteristics of the bone marrow products collected from patients and donors.³⁸

PURGING OF CELL POPULATIONS

For autologous HSCT, attempts to purge tumor cells from the inoculum have yet to demonstrate a survival advantage for the transplant recipient. On the other hand, in allogeneic HSCT, depletion of T cells from the

donor HSC product by various methods has proved an effective means of reducing the incidence of aGvHD and cGvHD, but this approach increases the risk of graft failure, opportunistic infections, and post-transplant relapse, effectively nullifying the advantage achieved by the lower incidence of GvHD.⁴ Higher doses of HSC, which can be achieved by the use of large quantities of PBSC or by combining marrow and PBSC components, will reduce the risk of graft failure. Fixed doses of lymphocytes, as opposed to maximal T-cell depletion may also reduce the risk of graft failure. Some centers are exploring partial T-cell depletion or post-transplant T-cell infusion in an effort to maintain the GvL effect while still reducing the morbidity and mortality of GvHD.

EXPANSION OF HSC PRODUCTS

Ex vivo expansion of HSC contained in UCB products is one potential mechanism to offset the low cell dose and delayed hematological recovery after transplantation.³² However, no expansion technique has yet achieved this goal, and such endeavors are complicated by the difficulty in identifying pluripotent HSC as opposed to lineage-committed progenitor cells. Furthermore, it is likely that expansion techniques effective for HSC expansion will result in T-cell depletion, resulting in other complications described above.

HEMATOLOGICAL RECOVERY

HSC engraftment encompasses two concepts: recovery of hematopoietic and immunological function of the bone marrow, and the rate at which this occurs. Delay in or failure of sustained engraftment after administration of a myeloablative-conditioning regimen greatly increases the morbidity and cost of the treatment and can result in the death of the patient.³⁵ Engraftment failure can occur as a result of inadequate quantities of HSC from poor collection or loss in post-collection processing, inadequate host support of the infused cells, post-transplant events or medications, or the immunologically mediated rejection of the allogeneic donor's cells (Fig. 82.3). Failure of engraftment is a very rare complication of autologous HSCT, and is likely only with poor preservation of HSC after collection. For allogeneic transplants, the risk of engraftment failure is proportional to the disparity between donor HLA and miHA, which occurs more commonly in unrelated-donor than in sibling-donor transplantation, and for mismatched rather than HLA-matched transplants. The risk of engraftment failure is also increased by the removal of T cells from the marrow inoculum because of the loss of the GvH effect, mediated by donor alloreactive cells against residual host immune cells.

Assessment of chimerism is important in evaluating poor marrow function after allogeneic HSCT. A fall in peripheral blood counts could indicate HvG-mediated rejection of the graft or early relapse after transplantation, or could be a result of post-transplant events, such as GvHD or viral infection. Documentation of stable persistence of donor cells will help discriminate between these possibilities. It is also important that sustained chimerism be demonstrated if DLI is to be used in the treatment of disease relapse after transplantation. The level of donor–host chimerism after allogeneic HSCT is currently demonstrated through the detection of sex chromosomes using fluorescent *in situ* hybridization (FISH) techniques, or for same-gender donor–patient pairs, through evaluation of single nucleotide tandem repeats (STR) using molecular analysis techniques (Chapter 101). Obviously, these studies are of no value in assessing engraftment after autologous HSCT.

Much of the emphasis in transplantation has been on myeloid engraftment, because initial patient survival depends on recovery of phagocytes and, to a lesser extent, platelets. Immune reconstitution, and in particular donor T-cell reconstitution, in HSCT patients is often hampered by the age of the recipient, the functional status of the thymus, the cytokine milieu at the time of transplant, and post-transplant immunosuppressive treatments. The thymus involutes rapidly during childhood, and in a normal adult is only able to contribute a very small portion to the mature T-cell compartment. Making matters worse, the thymic tissue may be damaged as a result of a myeloablative conditioning regimen, or it can also be a target of alloreactive donor T cells mediating GvHD. As a result, restoration of the T-cell compartment in patients is often slow, particularly for CD4 T cells, and may be suboptimal for many months to over a year. This situation, of course, endangers the ability of the patient to stave off opportunistic infections, and common complications arise from cytomegalovirus, herpes viruses, and fungal pathogens. If donor T cells are provided in the HSC inoculum, some reconstitution of the T-cell repertoire, mostly CD8 T cells, is provided by the mechanism of nonthymic homeostatic expansion, although the level of diversity may be limited. Experimentally, the administration of cytokines, such as IL-7, after HSCT can enhance thymic function and help donor T-cell reconstitution. Clinical trials are in progress to test this and other novel approaches with the same goal in mind. B-cell reconstitution, on the other hand, is less problematic in terms of the regeneration of the repertoire, although the ability to respond effectively to an infection with antibody production can still depend on the availability of antigen-specific CD4 T cells. Administration of immunoglobulin supplementation to patients with low IgG levels can prevent some of the infectious complications.³⁹ It should also be mentioned that HSCT patients who are conditioned with myeloablative regimens often attain high levels of donor chimerism in their lymphoid compartment within a few months of transplant. This often correlates with the ability of alloreactive donor T cells, capable of mediating GvHD, to target residual recipient HSC elements so that the primary source of *de novo* lymphoid reconstitution will be of donor origin. By the same token, high donor chimerism is also associated with a lower incidence of malignant relapse.

CONDITIONING REGIMENS

DOSE-INTENSIVE CHEMOTHERAPY

Many cancers treatable by HSCT exhibit chemotherapy sensitivity, and contemporary regimens produce initial tumor regression in most patients. However, for many patients regression may be partial or temporary, and survival is increased by only a few months or years. Chemotherapy-resistant tumor cells that will lead to subsequent relapse of disease may be present before initial treatment, or may develop by mutation during the period of treatment. However, for many cancers, including the hematological malignancies and certain solid tumors, resistance might be relative rather than absolute, justifying the administration of a dose-intensive cycle of chemotherapy with HSC support. In this simplified explanation, the infused HSC are intended only to rescue the patient from the marrow toxicity of the intensive regimen. The usual strategy that has evolved in the treatment of patients is 'debulking' with one or more cycles of conventional chemotherapy, followed by high-dose therapy as a late-intensification regimen. This strategy determines the sensitivity of the disease to chemotherapy;

also, patients who come to transplantation with lower burdens of disease generally achieve a better outcome. Randomized and nonrandomized studies in a number of malignancies such as lymphoma, leukemia, and myeloma demonstrate improved survival of patients who undergo autologous HSCT compared to salvage therapy with lower doses of drugs.

Total body irradiation (TBI) became the primary component of myeloablative conditioning regimens because of its efficacy in the treatment of hematological malignancies, its ability to treat sanctuary sites of disease such as the CNS, and for its immunosuppressive effects that can temper HvG rejection of the donor HSC. TBI is usually combined in sequence with chemotherapy agents such as cyclophosphamide or etoposide. The nonhematopoietic toxicities of TBI are reduced by fractionating the dose over several days, allowing higher total doses. Increasing the total dose of TBI decreases the risk of relapse, but increases the risk of transplant-related complications.⁴⁰ Often, these effects are offsetting and event-free survival remains the same. The primary dose-limiting toxicities of TBI include pneumonitis, veno-occlusive disease of the liver, renal impairment, and mucositis.

Busulfan-based regimens were developed as alternatives to TBI for the treatment of patients who had received prior dose-limiting radiotherapy, to avoid the effects of TBI on growth and development in children, and to eliminate the difficulty in scheduling patients to the limited availability of appropriate radiotherapy equipment. Initially, one of the limitations to the use of busulfan was the lack of an intravenous preparation, and wide variation in plasma levels with consequent effects on regimen-related toxicities, such as hepatic veno-occlusive disease, failure of engraftment, and relapse of disease.^{41–44} Close monitoring of plasma busulfan levels with dose adjustment reduces the risk of treatment failure, as does the recent availability of an intravenous formulation of this drug. A review of several studies to compare the use of busulfan and TBI found no statistically significant difference in overall or disease-free survival for patients with CML or AML.⁴⁵

The myeloablative conditioning regimens currently used have been tested in dose-escalation studies to achieve the maximal tolerated doses in otherwise healthy patients. Further incremental increases in drug or radiation doses, although reducing the risk of relapse, increase the risk of TRM offsetting any gain. New approaches include the addition of targeted therapies to the conditioning regimen, such as tumor-directed monoclonal antibodies or radioimmunoconjugates that will not increase the toxicity to other organs. Tandem transplantation with the combination of a dose-intensive regimen with autologous HSCT followed, after recovery from the immediate regimen-related toxicities, by allogeneic HSCT using a reduced-intensity regimen is a novel approach to combine the benefits of each transplant modality.

Nonmyeloablative regimens have been developed for allograft patients ineligible for myeloablative conditioning because of age or comorbid conditions, based on the concept that GvL responses, rather than high-dose cytoreductive therapy alone, are the key to preventing disease relapse. The primary requirement in developing a reduced-intensity regimen is the need to achieve adequate immunosuppression to permit the development of hematopoietic chimerism, which became feasible with the development of the purine analog family of drugs. A variety of regimens are available, including combinations of fludarabine with melphalan, and fludarabine with busulfan. These regimens can pose less immediate risk of regimen-related toxicities, and open the option of combining them with more aggressive immunotherapy in the form of delayed DLI to mediate a GvL effect. Among the least toxic are regimens that involve a single fraction of TBI. Storb et al.⁴⁶ proposed that the

HvG reaction leading to HSC rejection and the GvH reaction could both be modified by an appropriate immunosuppressive regimen administered after transplantation, allowing a reduction in the intensity of the pre-transplant conditioning regimen. This group demonstrated in both canine models and human trials the ability to achieve durable donor cell engraftment with low levels of TBI (2 Gy), if high-concentrations of cyclosporine and MMF were maintained after transplantation. Engraftment success in clinical transplantation was subsequently improved with the addition of the purine analog fludarabine.⁴⁷

■ HSCT FOR INDIVIDUAL DISEASES ■

ACUTE MYELOGENOUS LEUKEMIA (AML)

Most patients with AML will achieve a remission with an initial course of chemotherapy, but almost all will rapidly relapse if post-induction consolidation therapy is not administered. Even with appropriate therapy, the majority of patients (~65%) will relapse within 1–2 years, with the presence of cytogenetic abnormalities and the ability to achieve a CR with the initial course of therapy as predictors for long-term disease control. Numerous studies compared standard consolidation therapy to dose intensification with autologous or allogeneic HSCT. In general, autologous HSCT has not proved more effective than nontransplant intensive consolidation chemotherapy. Allogeneic HSCT had the lowest risk of relapse and, despite the higher transplant-related complications, in at least two major studies patients assigned to allogeneic transplantation achieved a significantly better disease-free survival (DFS) than those assigned to either chemotherapy or autologous HSCT. Allogeneic HSCT using related donors achieves about a 60–70% event-free survival, regardless of cytogenetic changes, and is the treatment of choice for patients with adverse risk cytogenetic findings or leukemia arising from prior chemotherapy or other marrow diseases.⁴⁸ In addition, a number of phase II studies of autologous HSCT for AML patients in second or later remission reported survival probabilities of ~35%, which is higher than what would be expected with standard chemotherapy regimens.⁴⁹

MYELODYSPLASTIC SYNDROMES (MDS)

MDS comprise a closely related but heterogeneous group of nonmalignant hematological disorders characterized by a clonal HSC abnormality that engenders variable degrees of cytopenia and frequent evolution to AML. Currently, allogeneic HSCT is the only treatment modality that can achieve long-term control of disease; autologous HSCT is not feasible because of the inability to collect normal HSC from these patients. The best results are seen in patients with earlier-stage disease,⁵⁰ complicating the decision to undertake this therapy rather than a watchful waiting approach with transplantation performed at the time of disease progression.

CHRONIC MYELOGENOUS LEUKEMIA (CML)

Allogeneic HSCT is an appropriate treatment for CML with long-term survival rates >80% for younger patients undergoing related donor transplantation within the first year after diagnosis. However, newly developed

inhibitors of the tyrosine kinase (TK) encoded by the Philadelphia chromosome, such as imatinib, have relegated transplantation to the treatment of patients with advanced disease, or the rare patient with CML not responsive to that targeted therapy. Unfortunately, the probability of long-term survival falls for patients who undergo allogeneic HSCT more than 1 year after diagnosis, and for patients with more advanced disease, and the effect of prior therapy with a TK inhibitor on the outcome of transplantation is not known. CML is highly responsive to the immunologic GvL effect and many patients in relapse can be salvaged by the administration of DLI. Limited numbers of patients with CML in chronic phase or with more advanced disease have been treated with autologous HSCT, and such treatment must be considered experimental. CML is a stem cell disease and the collection of normal HSC in most patients is unlikely. Of speculative interest is the collection of autologous cells after cytogenetic remission is achieved with use of a TK inhibitor for subsequent transplantation at the time of disease relapse.⁵¹

MYELOPROLIFERATIVE DISEASES (MPD)

MPD are nonmalignant clonal stem cell diseases and include Philadelphia (Ph) chromosome/BCR-ABL-positive CML (discussed above), polycythemia vera (PV), idiopathic myelofibrosis (IF), essential thrombocytosis (ET), chronic myelomonocytic leukemia (CMML), and atypical CML (Ph/BCR-ABL negative). These disorders display overlapping clinical features but have different natural histories and different therapeutic requirements. Allogeneic PBSC transplantation has been effective in these disorders. However, a prerequisite is an objective determination of candidacy because of the frequently long natural history of these diseases. Anemia, age, and cytogenetic abnormalities all predict poor survival in IF, for example, suggesting that patients with anemia and an abnormal karyotype should proceed to allogeneic HSCT. The extent of fibrosis of the marrow cavity appears irrelevant in the long-term success of treatment, and the fibrosis is frequently reversed within a few months of transplantation. Myeloablative allogeneic HSCT results in a high rate of durable engraftment and cure in approximately 50% of patients. Transplant-related complications associated with more advanced disease and age rather than disease recurrence account for the majority of treatment failures. More recently, reduced-intensity conditioning regimens have been shown to induce encouraging rates of engraftment and prolonged survival by exploiting the GvL effect mediated by immunocompetent donor T cells.

ACUTE LYMPHOBLASTIC LEUKEMIA (ALL)

In contrast to the treatment of children with ALL, only a small minority of adults with ALL are currently cured with induction and consolidation regimens. As with AML, adverse risk features include certain cytogenetic changes and the inability to achieve remission with initial remission-induction chemotherapy. Allogeneic HSCT in first remission is clearly effective in the management of ALL with adverse-risk cytogenetics such as t(4;11) or t(9;22) (Philadelphia chromosome).⁵² However, it is unclear whether transplantation is advantageous as part of the initial consolidation therapy in most individuals who lack adverse risk features, and furthermore, there is little to support the effectiveness of autologous HSCT, despite its theoretical potential. The lack of a prominent GvL effect in the treatment of ALL suggests that reduced-intensity regimens will be much less effective than fully ablative TBI-based regimens.

Autologous HSCT may be effective for a small proportion of patients who relapse and achieve a second remission.

CHRONIC LYMPHOCYTIC LEUKEMIA (CLL)

Because of the indolent nature, the long natural history, and the advanced age of most patients with CLL, many patients and physicians are reluctant to support aggressive treatment. Yet disease progression is inevitable, and the aggressiveness of this disease can be predicted by various features, including chromosome 17p and 11q deletions and the detection of ZAP-70 mutation and CD38 expression. Therefore, HSCT should be considered as a treatment choice, especially for younger patients or those with adverse features. The extensive infiltration of bone marrow by malignant lymphocytes has served to focus transplantation trials on allogeneic HSCT, or autologous HSCT with products collected in remission or purged *ex vivo*. In the few clinical studies that have been reported, high CR responses have been obtained with autologous HSCT patients after extensive *ex vivo* purging of bone marrow with multiple monoclonal antibodies, but relapses continue to be the most frequent source of late mortality, and autologous HSCT for CLL is mostly limited to clinical research protocols.

Allogeneic HSCT is very effective in the control of CLL.^{53,54} In the study from the Dana-Farber Cancer Institute of 162 patients with high-risk CLL who had undergone full myeloablative SCT between 1989 and 1999, 25 patients underwent related donor T cell-depleted HSC transplantation and 137 patients without sibling donors underwent autologous HSCT.⁵³ The 100-day mortality was similar in both groups at 4%. Overall survivals were also similar: 58% and 55% in the allogeneic and autologous cohorts, respectively. The probability of relapse after allogeneic HSCT was 68%, possibly as a result of the T-cell depletion and resultant loss of the GvL effect. The exquisite sensitivity of CLL cells to the GvL effect allows the use of reduced-intensity regimens with lower risks of regimen-related mortality in these (generally) older patients.⁵⁵ The Seattle transplant program described 64 patients with advanced CLL treated with a nonmyeloablative regimen of a single fraction of TBI, with or without fludarabine, and either related ($n=44$) or unrelated ($n=20$) HSCT.⁵⁵ The probability of relapse was only 26% and the probability of relapse-free survival was 52%.

MULTIPLE MYELOMA (MM)

MM is a malignancy of plasma cells with a median age at time of diagnosis of 65 years, and in which high-dose therapy, such as melphalan administered as a single agent, can give about a 22% CR rate, but ultimately, almost all patients relapse and succumb to the disease. Tandem autologous HSCT with two cycles of dose-intense therapy at 2–6-month intervals doubles the long-term survival rate.⁵⁶ Although autologous HSCT is not considered curative for this disease, the median duration of time without treatment after transplantation is 2–3 years, and ~15% of patients may not need treatment for progressive disease for 5 years or more, greatly improving their quality of life. Allogeneic HSCT after dose-intense therapy in the treatment of myeloma is characterized by unacceptable TRM, approaching 40% by day 100.⁵⁷ Use of a reduced-intensity conditioning regimen decreases the risk of TRM to less than 10%, but patients with advanced disease are unlikely to respond to this treatment.⁵⁸ The lower risk of complications with nonmyeloablative conditioning regimens has led to studies of tandem autologous HSCT, using an intensive chemotherapy regimen to achieve tumor debulking,

followed 2–6 months later by allogeneic HSCT using a reduced-intensity regimen to achieve the GvL effect. This approach to the treatment of MM is being studied in large multicenter trials, but a recent analysis of two trials involving patients with adverse risk features found no difference in time to disease progression for patients undergoing tandem autologous or tandem autologous/allogeneic HSCT.⁵⁹

NON-HODGKIN'S LYMPHOMA (NHL)

The lymphomas represent a diverse group of malignant diseases of B and T cells and comprise some of the slowest to some of the fastest-growing human malignancies, with a range of curability achieved using nontransplant therapies. As a group, the lymphomas exhibit a strong dose-response relationship to chemo-/radiotherapy, and the benefit of high-dose treatment with autologous HSCT is well established. The effectiveness of dose-intensive therapy with autologous HSCT avoids the morbidity of allogeneic HSCT and is the preferred approach for the majority of patients, with some prominent exceptions discussed below. Radiation-based regimens, including cyclophosphamide with TBI and etoposide plus TBI, have significant activity, but are frequently difficult to administer in that many patients have already been exposed to radiotherapy. Popular chemotherapy regimens include cyclophosphamide, BCNU, and etoposide (CBV), and BCNU, etoposide, Ara-C, and melphalan (BEAM). However, no single chemotherapeutic or radiation-based regimen has emerged as a superior treatment.

Low-grade NHL

Low-grade NHL, in general, exhibits a variable and prolonged natural course, with many patients not requiring treatment until symptoms or organ toxicity appear. Therefore, most experience with HSCT has been in patients after later relapses rather than at the time of initial diagnosis, delaying the potential for morbidity and mortality of dose-intensive therapy. Randomized studies comparing autologous HSCT to other nontransplant therapies for patients at the time of initial treatment have not been reported. However, a number of phase II and registry data have been published for autologous HSCT, and although response rates are high, a continuing pattern of relapse has been observed. In contrast, patients who undergo allogeneic HSCT experience a higher probability of TRM but a lower risk of relapse after transplantation. Indolent B-cell NHL appears to be very sensitive to the GvL effect of allogeneic HSCT, and using reduced-intensity regimens will result in fewer transplant-related complications. Overall, the difference in relapse rates between autologous and allogeneic HSCT could result from the possible reintroduction of lymphoma cells in the HSC product, but is more likely from the lack of a GvL effect of autologous HSCT. On the other hand, despite the small number of patients who have undergone autologous HSCT for indolent NHL after transformation to aggressive NHL, a large proportion achieved durable remissions. These results suggest that autologous HSCT is effective for this form of disease and should be considered for older patients or those lacking an allogeneic donor.

Aggressive NHL

Autologous HSCT is the standard of care for patients with B-cell NHL in first 'chemotherapy-sensitive' relapse.⁶⁰ The success of this therapy reflects the extent and the responsiveness of the disease to

chemotherapy at the time of transplantation, with relapse the major cause of treatment failure. In a randomized trial of high-dose therapy followed by autologous HSCT, the event-free survival at 5 years was significantly better than in a group receiving standard-dose treatment (46% versus 12%).⁶⁰ Furthermore, it is notable that no patients assigned to the conventional dose salvage therapy could be rescued at the time of second relapse with a delayed transplant. Therefore, excessive pre-transplant 'debulking' therapy and/or delays in transplant timing should be avoided.

There are other circumstances in which HSCT may be indicated, such as in patients who either respond slowly to initial therapy, have high-risk disease, are resistant to initial therapy, or are in relapse with chemotherapy-insensitive disease. The International Prognostic Index (IPI) identifies patients with aggressive NHL who have a high likelihood of relapse and poor overall survival with conventional first-line therapy. Several studies suggest that for patients with high-risk disease according to the IPI, the use of autologous HSCT therapy may be beneficial as part of the overall initial therapeutic strategy. On the other hand, results for patients with truly chemotherapy-refractory disease are poor.

Mantle cell lymphoma is known for its unremitting clinical course when treated conventionally, and has proved relatively resistant to high-dose treatment, especially when used as a salvage therapy. Mantle cell NHL appears to be exquisitely sensitive to the GvL effect of allogeneic HSCT, and reports of effective control of this disease with use of reduced-intensity conditioning regimens are encouraging.

Burkitt's lymphoma, Burkitt's-like lymphomas, and lymphoblastic lymphomas are high-grade NHL associated with relatively poor long-term survival rates. The role of both autologous and allogeneic HSCT in these disorders remains unclear. There are no convincing risk models that identify clear indications for transplantation in at the time of the first complete remission (CR1). Allogeneic HSCT should probably, therefore, be restricted to chemosensitive relapsed patients. The lack of a clear contributory benefit of GvL in these disorders suggests that for patients without bone marrow involvement and for whom a sibling is not available, autologous HSCT may provide a reasonable alternative to unrelated donor transplantation, particularly if the potential delay incurred by the donor search is likely to be considerable. Data from the European Group for Blood and Marrow Transplantation suggest that disease status at the time of transplant is the most important predictor of outcome in patients with high-grade disease.⁶¹ For Burkitt's and Burkitt's-like lymphoma, the 3-year actuarial overall survival rate was 72% for patients transplanted during CR1, compared to 37% in those with chemotherapy-sensitive relapse, and 7% in patients with disease unresponsive to chemotherapy. For patients with lymphoblastic lymphoma, the 6-year actuarial survival rate ranged from 63% in patients who were in CR1 to 15% in those who had resistant disease. Patients in CR2 had an intermediate survival rate of 31% at 6 years. These results with transplantation appear to be superior to conventional-dose salvage therapy.

T-cell lymphomas are less common entities. There is no well defined management strategy for these disorders, and treatment is based on the disease stage and immunopathologic grade. The relative results of treatment compared to the more common B-cell type treatment regimens is lower, although the comparison may not be appropriate, as T-cell diseases present at more advanced stages than do B-cell diseases. Particularly for virus-associated NHL, allogeneic HSCT is the preferred treatment approach.

HODGKIN'S DISEASE

Many patients with Hodgkin's disease will achieve a durable remission with nontransplant chemotherapy and/or radiation therapy, and algorithms for staging and treatment of this disease are well defined. Dose-intense therapy with autologous HSCT is available to those patients who do not achieve a remission or who relapse after initial therapy, and who will succumb without aggressive therapy. For patients who suffer a relapse after achieving a CR, the prognosis with conventional salvage therapy is directly related to the duration of the initial CR. The outcome for patients whose remission lasted less than 1 year is dismal with standard dose second-line treatments, and these patients are best treated with dose-intense chemotherapy and stem cell rescue. Approximately 40–50% of patients with Hodgkin's disease who suffer a relapse within 1 year will achieve a durable remission after autologous HSCT.

Patients with refractory Hodgkin's disease may achieve durable CR with dose-intense chemotherapy and autologous HSCT. Several studies have demonstrated that this approach can overcome drug resistance in Hodgkin's disease and lead to an overall survival rate of 34–50%.

Allogeneic HSCT is not a first choice for the treatment of relapsed Hodgkin's disease because of the higher transplant-related complications, despite the evidence of an effective GvL effect. With the regimen-related mortality of conventional myeloablative allogeneic HSCT approaching 60% in some reports of dose-intense regimens used to salvage patients after a failed prior autologous transplant, nonmyeloablative approaches are being actively studied as an alternative.⁶²

SOLID TUMORS

The skin and colonic mucosa are primary targets of both acute and cGvHD, and this suggests that allogeneic HSCT would be effective in the treatment of cancers of these organs. Yet allogeneic HSCT has not been shown to be effective in the control of these cancers, illustrating the discrimination between target antigens of normal tissues, such as the colonic crypt cells, and antigens expressed by tumors derived from these tissues. With the exception of allogeneic HSCT in the treatment of renal cell cancer, in which a graft-versus-tumor effect is clinically evident in some studies,^{63, 64} transplantation in the treatment of solid tumors such as neuroblastoma, Wilms' tumor, and germ cell tumors is limited to autologous HSCT after one or more cycles of dose-intense chemotherapy.

FUTURE DIRECTIONS

Advances in HLA typing, chemotherapy conditioning regimens and supportive care have greatly reduced the toxicity of both autologous and allogeneic HSCT, allowing older patients (those more likely to suffer from malignant hematological disorders) to receive this potentially curative therapy. Although the diseases treatable by HSCT are characterized by dose sensitivity, currently available dose-intense conditioning regimens have been pushed to maximal tolerable doses. New approaches to the treatment of these malignancies include the addition of therapies that are targeted to the malignancy, such as radioimmunoconjugates that will add minimal toxicity to other organs. The availability of reduced-intensity regimens permits tandem transplantation, using dose-intense therapy with autologous HSCT to achieve maximal tumor cell debulking, followed

after recovery from transplant-related toxicities by allogeneic HSCT, using a reduced-intensity regimen to achieve an immunological GvL effect. This approach may be especially effective in the treatment of diseases most sensitive to this immunological benefit of allogeneic HSCT. Finally, the ability to use HSCT as a platform for protein or cellular-based vaccination strategies is conceivable, and is the subject of considerable interest.

Stem cell transplantation and immune reconstitution in immunodeficiency

Luigi D. Notarangelo, Evelina Mazzolari

83

INTRODUCTION

Following the discovery of the major human leukocyte antigens (HLA) locus in 1968, human stem cell transplantation (HSCT) came into practice to provide treatment for a variety of congenital and acquired disorders. Remarkably, this new era in medicine was marked by the successful use of HSCT to cure an infant affected with severe combined immune deficiency (SCID) in 1968.¹

For many years, the successful use of HSCT in severe primary immune deficiencies was largely restricted to HLA-identical transplants, as HSCT from mismatched related family donors (usually represented by haploidentical parents) was followed by severe complications, and graft-versus-host disease (GvHD) in particular. In the late 1970s it was demonstrated in animal models that removal of mature T lymphocytes from the graft obtained from mismatched related marrow allowed successful reconstitution upon injection into lethally irradiated recipient animals. This important achievement opened the way to a broader use of HSCT in severe forms of primary immunodeficiency (PID). More recently, the availability of stem cells from volunteer matched unrelated donors (MUD) and from cord blood has further increased the successful application of HSCT in individuals with PID (Table 83.1).

■ HEMATOPOIETIC STEM CELL TRANSPLANTATION: GENERAL CONSIDERATIONS ■

SOURCES OF HEMATOPOIETIC STEM CELLS FOR TRANSPLANTATION

Several sources of hematopoietic stem cells are available for transplantation (Table 83.2). In particular, hematopoietic stem cells can be retrieved from bone marrow, peripheral blood, or cord blood. Bone marrow stem cells are most commonly obtained by multiple aspirations along the iliac crests, usually while the donor is under general anesthesia. The volume of bone marrow obtained may vary between 500 mL and 1 L, depending on

the type of transplant (HLA-identical or T-cell depleted) and on the weight of the recipient. In the case of HLA-identical transplantation, the marrow stem cells are then injected intravenously without further manipulation into a central line in the recipient. In the case of mismatched transplantation, bone marrow cells are T-cell depleted *in vitro* (see below); stem cells are then enumerated and injected intravenously.

Hematopoietic stem cells can also be retrieved from peripheral blood, upon *in vivo* administration of granulocyte-colony-stimulating factor (G-CSF) to the donor, usually at a dose of 10 µg/kg/day for 5 days, which allows mobilization of stem cells. In this case, stem cells are purified by positive selection (see below), enumerated and injected.

Finally, cord blood is another rich source of hematopoietic stem cells. At birth, cord blood is collected in heparinized medium and stored in liquid nitrogen, and small aliquots are preserved for HLA typing. Whenever sufficient compatibility is identified between a patient and a stored cord blood, the latter is thawed and injected into the recipient without further manipulation. With this procedure, the number of stem cells that can be transplanted is dictated by their concentration in the cord blood sample, and by the volume of the sample itself. More recently, *in vitro* expansion of cord blood stem cells has been attempted in order to overcome this limitation.

DONOR SELECTION AND MANIPULATION OF THE GRAFT

HSCT from a related HLA-identical donor

The use of unfractionated stem cells from an HLA-identical sibling offers the best prospect for rapid engraftment and immune reconstitution. In such cases, in fact, the HLA identity between recipient and donor minimizes the risk of GvHD. Furthermore, the mature T cells contained in the graft provide a first line of immune reconstitution after transplant, as they may expand and lead to a rapid increase in the number of circulating T lymphocytes as early as 2 weeks after HSCT. Finally, relatively few stem cells are required to achieve engraftment and immune reconstitution following related HLA-identical HSCT, although even in this setting a larger dose may facilitate immune reconstitution.

Table 83.1 Hematopoietic stem cell transplantation for primary immune deficiencies in Europe 1968–2004 (Data from the European SCETIDE Registry, courtesy of Paul Landais and Alain Fischer)

Type of Immunodeficiency	Patients with genotypically identical related donor	Patients with phenotypically identical related donor	Patients with mismatched related donor	Patients with matched unrelated donor	Total number of patients
SCID	126	61	367	58	612
Omenn's syndrome	14	9	29	10	62
MHC class II deficiency	20	10	26	5	61
PNP deficiency	2	1	1	1	5
CD40L deficiency	9	0	1	21	31
Other forms of CID	35	7	44	29	115
Di George syndrome	1	0	0	1	2
Other T-cell deficiencies	5	1	5	4	15
WAS	45	8	47	50	150
FHL	26	6	37	19	88
XLP	3	0	1	7	11
Chediak–Higashi syndrome	10	5	3	4	22
Griscelli syndrome	6	2	1	1	10
Agranulocytosis	3	0	2	3	3
CGD	25	0	0	5	30
LAD	13	2	16	1	32
IFN- γ receptor deficiency	2	1	1	0	4
Other phagocytic disorders	2	0	0	1	3
All defects	347	113	581	220	1261

SCID, severe combined immunodeficiency; MHC, major histocompatibility complex; PNP, purine nucleoside phosphorylase; CID, combined immune deficiency; WAS, Wiskott–Aldrich syndrome; FHL, familial hemophagocytic lymphohistiocytosis; XLP, X-linked lymphoproliferative disease; CGD, chronic granulomatous disease; LAD, leukocyte adhesion deficiency.

HSCT from a haploidentical donor

Unfortunately, the option of related HLA-identical HSCT is limited to only a minority of patients. When no such donor is available, stem cell transplantation from a haploidentical parent should be considered, particularly in infants with SCID. The rationale of haploidentical HSCT is based on the ability of donor-derived stem cells to repopulate the recipient's vestigial thymus and give rise to fully mature T lymphocytes. Indeed, this is a life-saving procedure which has been successfully applied to several hundreds of infants with SCID.^{2, 3} However, it requires careful removal of T lymphocytes from the graft, as these would otherwise cause severe GvHD. Several methods are now available to attain T-cell depletion.³

Soybean lectin allows agglutination of the majority of mature marrow cells that can be removed by sedimentation. This step is followed by further depletion of T lymphocytes by rosetting with sheep erythrocytes (E-rosetting technique) and density gradient centrifugation. Importantly, T-cell depletion by soybean lectin agglutination and E-rosetting

maintains all immature marrow cells in the final preparation. In general, the procedure requires a relatively large collection (approximately 1 L) of bone marrow from the donor.

T-cell depletion can also be achieved by incubation of the marrow with monoclonal antibodies to T lymphocytes plus complement. Campath-1G, Leu 1 and other monoclonal antibodies have been used for this purpose, but the degree of T-cell depletion that is achieved is often less effective than with soybean lectin and E-rosetting, possibly because of modulation of antigen expression on the surface of T lymphocytes. Consequently, there is a higher probability that GvHD may develop.

Positive selection of CD34⁺ cells using monoclonal antibody affinity columns or immunomagnetic beads has been widely used in recent years. However, this approach removes immature CD34⁺ cells and other cells (especially stromal marrow cells) that may facilitate stem cell engraftment. Following the recognition that CD133 is expressed on primitive

KEY CONCEPTS**SOURCES OF STEM CELLS AND SELECTION OF DONORS FOR HEMATOPOIETIC STEM CELL TRANSPLANTATION IN PRIMARY IMMUNODEFICIENCIES**

- >> Sources of hematopoietic stem cells for transplantation include bone marrow, peripheral blood, and cord blood.
- >> If the donor is a genotypically HLA-identical sibling, unmanipulated bone marrow is used as source of stem cells.
- >> Whenever the donor is HLA-mismatched to the recipient, T-cell depletion must be performed to eliminate mature T lymphocytes from the graft. Methods for T-cell depletion of the bone marrow include:
 - Use of soybean lectin agglutination (\pm E-rosetting)
 - Depletion with monoclonal antibodies plus complement
 - Positive selection of stem cells.
- >> Cord blood is a rich source of stem cells. However, the volume of cord blood is limited, so that its use is mainly restricted to young patients.
- >> The number of volunteers included in Bone Marrow Donor Registries is expanding. Consequently, there is a continuous increase in the number of matched unrelated donor (MUD) transplantations performed for patients with primary immunodeficiencies.
- >> Whenever unrelated cord blood or MUD stem cells are used, conditioning regimen is usually given to the recipient prior to transplantation, in order to facilitate engraftment of donor stem cells.
- >> Therapeutic options for patients with SCID include transplantation from HLA-genotypically identical donor, or from mismatched related donors. Recently, transplant from MUD has also been successfully used in SCID infants under stable conditions.
- >> For other forms of primary immunodeficiencies, whenever no related HLA-identical donor is available, search for a MUD or an unrelated cord blood should be started, as the results of such transplants are better than from related mismatched donors.

hematopoietic progenitors, positive selection of CD133⁺ cells with immunomagnetic beads has also been proposed.

Selection of the best donor is another important aspect of T cell-depleted haploidentical HSCT for SCID. In general, the donor is represented by one of the parents, as the volume of bone marrow that can be collected is much higher than it would be in case a haploidentical sibling served as donor. It is also important to recognize that maternal T-cell engraftment is a common finding in infants with SCID. In a survey of 121 SCID patients, Müller et al.⁴ identified 48 cases (39.7%) with maternally derived T lymphocytes. In such cases, T cell-depleted HSCT should be performed using the mother as donor if possible, as transplantation from the father might cause graft-versus-graft reaction.

Table 83.2 Sources of hematopoietic stem cells for transplantation**HSCT from a related donor**

Bone marrow from an HLA-genotypically identical sibling
 Bone marrow from an HLA-phenotypically identical family member
 Bone marrow from a haploidentical parent

 T cell-depleted by negative selection with monoclonal antibodies
 Positive selection of CD34⁺ cells (\pm CD133⁺ cells)

HSCT from a matched unrelated donor

Unmanipulated bone marrow
 T cell-depleted bone marrow by means of positive selection of CD34⁺/CD133⁺ cells
 Positively selected peripheral blood CD34⁺ cells

HSCT from unmanipulated related or unrelated cord blood**In utero haploidentical HSCT**

The identification of a growing number of immunodeficiency-causing genes has resulted in continuous improvement in prenatal diagnosis, which can now be accomplished on chorionic villi DNA at 10–11 weeks of gestation in most cases of severe immunodeficiency. This has prompted a prenatal transplantation of parental positively-selected CD34⁺ stem cells in fetuses affected with SCID. This novel strategy has overcome previous largely unsatisfactory experience with fetal liver and other stem cells.

The technique used for in utero HSCT includes injection of purified CD34⁺ cells into the fetal peritoneum under ultrasound guidance.

The rationale underlying in utero HSCT includes a lower risk of graft rejection due to decreased fetal immunocompetence (although this consideration is not relevant in the case of fetuses with SCID); a presumed induction of tolerance to paternal antigens (which might favor successful engraftment after postnatal transplantation from the same donor); the predicted competition between donor and autologous stem cells at a time when several empty niches should be available for stem cell engraftment; the potential ability to provide pre-emptive treatment (thus reducing the risk of postnatal infection); and the lower cost of the procedure, which does not require prolonged hospitalization. On the other hand, in utero HSCT exposes to the potential risks of fetal loss and of GvHD. Finally, if maternal T cells had engrafted into the fetus with SCID, transplantation of paternal CD34⁺ cells might cause graft-versus-graft reaction.

In utero HSCT has been attempted in several infants with severe immunodeficiencies, most notably SCID.⁵ Five of these transplants have been performed at the authors' institution. All three cases with B⁺ SCID (two of which were due to γ c deficiency and one to IL7R α deficiency) have survived with evidence of T-cell reconstitution; of the two cases with B⁻ SCID, one has failed to achieve immune reconstitution, in spite of two additional boosting transplants from the same donor (the father) after birth. This patient eventually died of B-cell lymphoproliferative disease (BLPD) after a MUD HSCT. In the fifth patient (with B⁻ SCID due to RAG2 mutation), thymopoiesis has rapidly declined and the patient remains profoundly lymphopenic. Although the overall results of the procedure appear to be

influenced by the nature of the underlying disease, the use of in utero HSCT for SCID is now largely unjustified, in consideration of the fact that early postnatal HSCT for SCID leads to long-term survival in 97% of cases.^{3,6} Furthermore, the observation that engraftment is restricted only to cell lineages that were missing in the affected fetus is a strong argument against the use of in utero HSCT for treatment of PID other than SCID.

HSCT from matched unrelated donors

Since the first successful experience with this technique, performed in 1977 in an infant with SCID,⁷ HSCT from MUD has been increasingly used to treat severe primary immunodeficiencies. In particular, use of MUD HSCT has been shown to be more effective than T cell-depleted HSCT in patients with immunodeficiencies other than SCID.² More recently, it has been successfully used also in infants with SCID.^{8,9}

Transplantation from MUD has been facilitated by the increasing number of volunteer donors included in registries worldwide. In addition, advances in the quality of the techniques used for HLA typing permits optimization of the identification of a MUD, and a reduction in the risk of GvHD. As of April 2006, more than 10 million donors were included in the Bone Marrow Donors Worldwide (BMDW) registry. At present, it takes 3–4 months on average to identify a MUD. However, the probability of finding a suitable donor is lower for selected ethnic or racial groups that are poorly represented among volunteer donors.

Importantly, MUD HSCT requires the use of a preparative chemotherapy regimen in the recipient (even in the case of SCID) and graft-versus-host prophylaxis (because of more likely disparity between donor and recipient at minor histocompatibility loci), whereas neither one is necessary for related HLA-identical HSCT in SCID infants.

HSCT using unmanipulated cord blood

As opposed to MUD, stored cord blood is readily available as a source of stem cells for transplantation. In addition, it appears that the risk of GvHD is lower when using cord blood than with MUD, so that some HLA disparity with the recipient can be tolerated. On the other hand, a major limitation of cord blood remains the number of cells contained in any defined unit. However, this is not usually a problem for transplants performed in infants with SCID or other severe forms of immunodeficiency, owing to the low weight of the recipient. Indeed, unrelated umbilical cord stem cell transplantation has been successfully used in several patients with severe primary immune deficiencies.^{2,3,9,10} In practice, an unrelated hematopoietic stem cell donor should be simultaneously searched for in cord blood banks and in bone marrow donor registries for patients lacking an HLA-identical sibling hematopoietic stem cell donor. The option of performing cord blood transplants should be based on the urgency of the transplant, the cell dose required, and the number of HLA disparities. Like HSCT from MUD, transplantation using unrelated cord blood usually requires pre-transplant conditioning and GvHD prophylaxis, irrespective of the underlying disease.

COMPLICATIONS OF HEMATOPOIETIC STEM CELL TRANSPLANTATION

A variety of complications may compromise the success of HSCT. Among these, incompatibility between donor and recipient may lead to graft rejection by the host immune system or, alternatively, to GvHD,

KEY CONCEPTS

REJECTION OF DONOR STEM CELLS BY THE HOST IMMUNE SYSTEM AND REACTION OF DONOR'S T LYMPHOCYTES TO THE HOST

- >> Host T cells are responsible for the elimination of donor stem cells, regardless of the degree of HLA compatibility. Other than in patients with SCID, a chemotherapy-based conditioning regimen must be used prior to transplantation in order to allow for donor stem cell engraftment.
- >> If T cells are present in the graft, and especially if there is HLA incompatibility between the donor and the recipient, the donor's T lymphocytes may react to host alloantigens and cause graft-versus-host disease (GvHD).
- >> Risk factors for GvHD include HLA-mismatch between donor and recipient, older age at transplantation, gender mismatch, and previous viral infections.
- >> GvHD may develop early after transplantation (acute GvHD), or at 100 days or more after transplant (chronic GvHD). GvHD is one of the major causes of death and long-term disability after stem cell transplantation.
- >> Prevention is the best approach to the management of GvHD. Prevention of GvHD is based on selection of optimal donor and vigorous T-cell depletion in the case of HLA mismatch between the donor and the recipient. Immunosuppressive drugs, such as cyclosporine A, are another potent form of prevention of GvHD.

caused by alloreactivity of donor-derived lymphocytes to the recipient's cells. Furthermore, the use of a conditioning regimen is often responsible for toxicity that may affect several organs. In addition, myeloablative regimens cause anemia, thrombocytopenia, and leukopenia. Consequently, supportive treatment with red blood cell and platelet transfusions is necessary during the aplastic phase. Finally, the leukopenia may expose to an increased risk of infections. The frequency and severity of these complications depend on the type of transplant, the possible use of a conditioning regimen, and specific considerations related to the underlying disorder and to the clinical status of the recipient prior to transplantation.

Graft rejection

Graft rejection reflects the presence of immunocompetent cells in the host that specifically recognize and react to donor-derived stem cells. Several factors influence the likelihood of graft rejection, in particular (a) the degree of immunocompetence of the host; (b) the degree of HLA disparity between donor and recipient; (c) the number of stem cells infused; (d) the type of conditioning regimen used; and (e) the possible pre-sensitization of the host to donor histocompatibility antigens.

In the case of infants with SCID, graft rejection is unlikely because of the profound immunodeficiency that characterizes these conditions. Conversely, in other forms of primary immunodeficiency there is sufficient immune function in the host to allow for rejection of donor-derived

stem cells, unless an appropriate conditioning regimen is used prior to HSCT.

In children, the most commonly used preparative regimen consists of busulfan and cyclophosphamide, with or without the addition of anti-thymocyte globulin (ATG). In some forms of congenital immunodeficiencies, such as phagocytic or hemophagocytic cell disorders, a more aggressive conditioning regimen is often used that includes additional drugs.

On the other hand, infants with pre-existing organ damage are highly exposed to the toxic effects of drugs conventionally used in the conditioning regimen. In these cases, nonmyeloablative regimens (e.g., the association of fludarabine and melphalan) have often been preferred.¹¹ A more vigorous GvHD prophylaxis is often necessary if nonmyeloablative conditioning is used, because of the higher risk of GvHD.

Acute graft-versus-host disease

Acute GvHD (aGvHD) is the result of alloreactivity of donor-derived T lymphocytes to the recipient's antigens, and is one of the most severe complications of HSCT. It may occur as early as 1 week after HSCT and is potentially fatal. Clinical manifestations of aGvHD include high-grade fever, maculopapular skin rash (that tends to be confluent), diarrhea, and liver abnormalities (hepatomegaly, elevated liver enzymes, increased levels of conjugated bilirubin).¹² The disease may progress to severe skin manifestations, with exfoliative dermatitis, and significant liver and gut damage (with intractable watery diarrhea, protein-losing enteropathy, and abdominal pain). In the most severe cases, leakage of intravascular fluids into the interstitium (so-called 'third space filling'), leads to generalized edema. Bone marrow aplasia, and a high susceptibility to infections (including reactivation of herpes virus infections) are also often observed in severe aGvHD. The severity of aGvHD is evaluated according to grading (Table 83.3). The major risk factors for aGvHD include HLA mismatch between donor and recipient; older age of the recipient at HSCT; gender mismatch; or a prior herpes virus infection.¹² However, aGvHD may also be observed following related HLA-identical HSCT, particularly when conditioning regimen is used. Finally, transfusion-associated aGvHD is a very severe complication after HSCT that can be effectively prevented by using irradiated (150–300 Gy) and filtered blood derivatives.

Chronic graft-versus-host disease

GvHD is defined as chronic (cGvHD) if symptoms persist or appear after 100 days since the time of transplantation. The clinical manifestations of cGvHD include skin changes (scleroderma-like lesions, hyperpigmentation, hyperkeratosis, skin atrophy, ulcerations), tissue fibrosis and limitation of joint motility, fibrosis of exocrine glands ('sicca syndrome'), fibrosis of lungs and liver, increased susceptibility to infections, immune dysregulation and autoimmunity. Consequently, cGvHD poses a major burden on the patient's quality of life, and may even be fatal.

Although the incidence of cGvHD is lower in children than in adults treated by allogeneic HSCT, the risk factors and the spectrum of clinical manifestations are similar.¹³

Acute GvHD represents a major risk factor for cGvHD, yet cGvHD may be observed even without a preceding aGvHD, and it does not represent merely the continuation of aGvHD, when present. Older age of the recipient at HSCT, transplantation from a multiparous female

Table 83.3 Grading of acute GvHD

Grade 1:	1+ to 2+ skin rash, without involvement of the gut, and with absent or minimal (no more than 1+) liver involvement
Grade 2:	1+ to 3+ skin rash, with either 1+ to 2+ gut involvement and/or 1+ to 2+ liver involvement. Fever is often observed
Grade 3:	2+ to 4+ skin rash, with 2+ to 4+ gut involvement with or without 2+ to 4+ liver involvement. High-grade fever and deterioration of general conditions are also observed
Grade 4:	as in grade 3, but with severe deterioration of the general conditions

donor into a male recipient (with reactivity to Y chromosome-associated antigens), and incompatibility at minor histocompatibility loci represent additional risk factors for cGvHD.¹³ Furthermore, it appears that use of peripheral blood stem cells carries an increased risk of cGvHD compared to the use of bone marrow stem cells.

Prevention of GvHD

Prevention is the most effective approach to GvHD, and the use of a fully matched donor represents the best method of prevention. Alternatively, if a related HLA-mismatched donor is used for transplantation, it is essential that the graft is vigorously T-cell depleted.

Whenever a conditioning regimen is used in the transplantation protocol, pharmacological prophylaxis of GvHD must also be included, even in the case of HSCT from a related HLA-identical donor. The most commonly used approaches to prevent GvHD include cyclosporine A daily for 6 months, or methotrexate (15 mg/m² on the first day after HSCT, and then 10 mg/m² at days 3, 6, and 11 after transplant), or a combination of the two. ATG is also commonly used to prevent GvHD.

Attempts to prevent cGvHD have been less satisfactory. In particular, the use of prolonged immunosuppression after transplant does not reduce the incidence of cGvHD.

Treatment of GvHD

Once GvHD has developed, treatment is based mainly on the use of immunosuppressive drugs, including steroids, ATG, mycophenolate mofetil, cyclosporine A, and a variety of monoclonal antibodies directed to human T-lymphocyte antigens (e.g., anti-CD3) or to Th1-type cytokines (e.g., anti-TNF- α) and cytokine receptors (anti-CD25, daclizumab). These drugs are usually effective for mild and moderate forms of aGvHD, but their efficacy in severe aGvHD is limited.

Treatment of cGvHD is also based on immunosuppression, but with limited efficacy.¹³ Topical steroids and calcineurin inhibitors may alleviate mucosal and skin symptoms. Systemic steroids have been shown to improve survival, but at the risk of significant adverse effects. Ursodeoxycholic acid may be useful in cGvHD with significant liver involvement. Extracorporeal photopheresis can be used, with the aim of inducing tolerance; typically, its benefits, if present, are delayed until 2–3

months after the start of treatment. The use of hydroxychloroquine, mycophenolate mofetil, anti-TNF- α monoclonal antibody, and etanercept (a recombinant form of soluble TNF receptor) remains at present investigational.

An interesting approach under consideration is based on the adoptive transfer of regulatory T cells (Treg), which may improve tolerance and prevent autoimmune responses.

Infections

Infections are one of the major complications following HSCT. Patients with severe primary immunodeficiency are intrinsically highly susceptible to infection. For infants with SCID and other forms of combined immunodeficiency, viral and opportunistic infections may develop prior to transplantation and are one of the factors that adversely affect the outcome of HSCT itself.² Similarly, treatment-refractory bacterial – and especially fungal – infections may compromise survival after HSCT in children with phagocytic disorders.¹⁴ Regardless of the type of underlying primary immunodeficiency, T cell-depleted HSCT carries a high risk of infections because of the longer time needed to achieve immune reconstitution. Furthermore, the use of a pre-transplant conditioning regimen resulting in myeloablation and immunosuppression, and GvHD prophylaxis, contributes to the increased susceptibility to infections after HSCT.

Strict isolation of the patient during and after HSCT, and prophylactic administration of antibiotics, have been associated with a better survival rate, particularly after related HLA-mismatched transplantation for SCID.² In spite of this, infections remain the major cause of death. Challenging viruses in infants with SCID include adenovirus, cytomegalovirus (CMV), parainfluenzae III virus, and Epstein-Barr virus (EBV), although several drugs (e.g., acyclovir, ganciclovir, foscarnet, cidofovir) are now available that give good results especially against CMV.¹⁵ Filtering of blood derivatives removes leukocytes and thus reduces the risk of transfusion-associated infections, such as CMV. Viral infection after HSCT may cause interstitial pneumonia, enteritis, and also encephalitis. EBV may also cause B-cell lymphoproliferative disease (BLPD), especially after T cell-depleted HLA-mismatched transplantation, in particular in patients with Wiskott-Aldrich syndrome (WAS). This complication is now often treated successfully with *in vivo* administration of anti-CD20 monoclonal antibody (rituximab).

Pneumocystis jiroveci is a common cause of pneumonia in severely immunocompromised patients. Treatment is based on intravenous cotrimoxazole (20 mg/kg/day).

Aspergillus infection is a severe complication in patients with chronic granulomatous disease (CGD) and in profoundly neutropenic patients.¹⁴ Voriconazole offers some advantage over liposomal amphotericin B for the treatment of invasive aspergillosis, whereas prophylactic itraconazole reduces the incidence of fungal infections in patients with CGD prior to transplantation.

Bacterial infections are usually amenable to successful treatment, if the pathogen is identified and appropriate and aggressive use of antibiotics is initiated. Prophylactic administration of immunoglobulins following HSCT contributes to reduce the frequency and severity of infections.

Finally, the clinical manifestations of the infection tend to be more severe when initial signs of immune reconstitution appear, as the latter facilitates the development of inflammatory reactions both at the site of infection and systemically.

Toxicity related to conditioning regimen

Chemotherapeutic agents that are used in the conditioning regimen of HSCT are often a cause of significant toxicity. In particular, radiomimetic drugs such as busulfan may cause lung damage, which is often difficult to distinguish from pulmonary infection.

Chemotherapeutic drugs that damage the liver vascular endothelium may cause veno-occlusive disease (VOD), which is marked clinically by painful hepatomegaly, jaundice, ascites, fluid retention, and weight gain, and may ultimately result in fatal multiorgan failure (MOF). Defibrotide and recombinant tissue plasminogen activator (rTPA) are effective in the treatment of VOD.^{16,17}

Pre-transplant conditioning may also lead to hormonal disturbances. Early complications include inappropriate secretion of anti-diuretic hormone, especially when cyclophosphamide is included in the conditioning regimen. Long-term hormonal complications are more common when total body irradiation (TBI) is used. However, cyclophosphamide may cause delayed puberty or sterility, and thyroid dysfunction is frequently observed, even in patients who have not received TBI. In contrast, effects on final height are not significant when regimens other than TBI are used.

■ HSCT FOR THE TREATMENT OF PRIMARY IMMUNODEFICIENCY DISORDERS ■

In 1968, the first successful experience with HLA-identical HSCT in SCID was reported.¹ Shortly thereafter, partial success was achieved also with HSCT in a child with WAS.¹⁸ Since then, over 1300 transplants have been performed in patients with primary immunodeficiencies, most of whom were children with SCID.^{2,3} The increasing number of transplants over the years reflects the improved outcome of the procedure as a result of advances in supportive and critical care before and after HSCT, as well as of increasingly improved strategies for T-cell depletion applied for related HLA-mismatched HSCT, and of the greater availability of MUD and cord blood for transplantation.

HSCT FOR SCID

General considerations

SCID is a medical emergency and is uniformly fatal unless diagnosed promptly and treated successfully. With few exceptions, in which alternative strategies (gene therapy, enzyme replacement therapy) can be used, allogeneic HSCT represents the only and most effective form of treatment (i.e., cure) for these disorders.

SCIDs are also a unique situation in which the virtual lack of T lymphocytes strongly impairs the ability of the recipient to reject the graft. Consequently, immune suppression is not required in these patients. Furthermore, no conditioning regimen is necessary for infants with SCID who have a related HLA-identical donor. Some transplant centers in the USA adopt the same policy also for T cell-depleted mismatched HSCT, whereas such transplants in Europe are usually performed with use of a preparative regimen, unless the patient's conditions are so severe as not to allow the use of chemotherapeutic drugs. Avoiding the use of

CLINICAL PEARLS

CONSIDERATIONS OF STEM CELL TRANSPLANTATION UNIQUE TO SCID

- >> Patients with SCID are strongly impaired in their ability to reject allogenic cells, including stem cells. Therefore, no chemotherapy is required in these patients in order to achieve T-cell reconstitution following stem cell transplantation.
- >> The quality and the kinetics of T-cell reconstitution following stem cell transplantation depend on the type of transplant. If unmanipulated bone marrow from genotypically HLA-identical related donor is used, mature T cells contained in the graft expand as early as 2 weeks after transplantation and provide a rapid source of immune competence. Following unmanipulated MUD transplantation, however, drugs used in conditioning regimen decrease the degree of early expansion of donor-derived T cells.
- >> Appearance of naïve T cells occurs only at 3 months or more after transplantation, regardless of the degree of HLA-matching between donor and recipient. Consequently, following haplo-identical transplantation there is a prolonged period during which the recipient remains lymphopenic and at high risk of infections.
- >> In the absence of pre-transplant conditioning, following haploidentical transplantation for SCID, engraftment is usually restricted to T (and sometimes NK) lymphocytes. This may cause persistent B-cell dysfunction.
- >> Patients with NK⁺ SCID may show some ability to reject stem cells from HLA-mismatched donors. For these reasons, many centers (particularly in Europe) include pre-transplant conditioning for haploidentical, MUD, or unrelated cord blood transplantation for SCID

conditioning regimens eliminates the risk of drug-related toxicity, and reduces the chance of developing GvHD. On the other hand, the reason why European centers tend to use conditioning regimens prior to mismatched or MUD HSCT for SCID is the resistance to engraftment that may be observed, particularly in SCID with residual autologous NK lymphocytes. Furthermore, unconditioned mismatched related HSCT has been shown to lead to split chimerism, which may affect the quality of immune reconstitution.

Survival following HSCT for SCID

The two largest series of SCID patients treated by HSCT in Europe and at a single center in the USA include 475 and 138 cases, respectively.^{2,3} In the European study, which includes transplants performed from 1968 to 1999, 153 patients had received HSCT from a genotypically ($n=104$) or phenotypically ($n=49$) identical related donor, with an overall survival rate of 77%. This figure is clearly superior to the 54% survival rate observed among 294 patients who had received related HLA-mismatched HSCT. Finally, in this report only 28 patients had received HSCT from a MUD, and 63% were alive.² At the authors' institution, among 69 infants with SCID treated by HSCT, overall survival rates following related HLA-identical, MUD, and T cell-depleted haploidentical HSCT

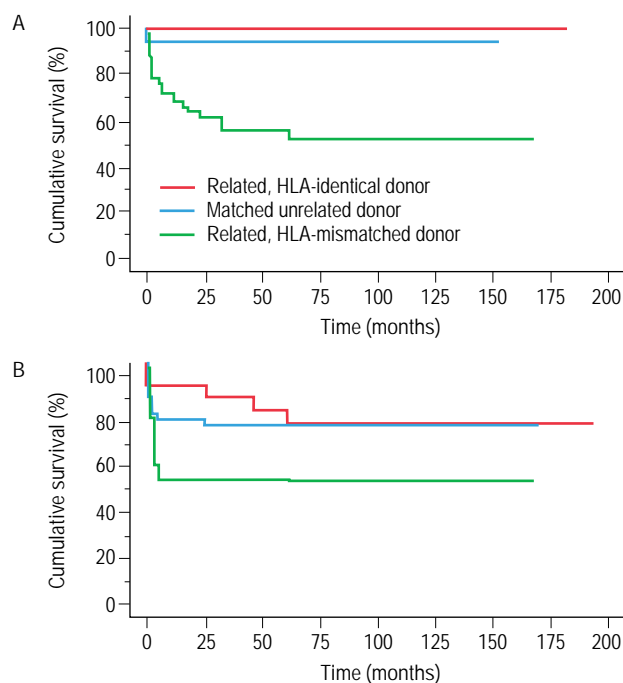

Fig. 83.1 Kaplan–Meyer survival curve for 148 consecutive children with primary immunodeficiency who have received hematopoietic stem cell transplantation (HSCT) at the authors' institution. **(A)** survival after HSCT in 69 infants with SCID, 12 of whom have received related HLA-identical HSCT, 41 a mismatched related transplant, and 16 a MUD HSCT. **(B)** Survival after HSCT in 79 children with immunodeficiency other than SCID. Of these patients, 23 have received related HLA-identical HSCT, 13 a mismatched related HSCT, and 43 a MUD HSCT

were 100%, 94%, and 52%, respectively (Fig. 83.1A). In the most recent report from Buckley and collaborators,³ the overall survival rate after HSCT for SCID was 78%. In particular, all 16 recipients of related HLA-identical HSCT were reported to be alive, as were 91 of 122 (75%) recipients of T cell-depleted related HLA-mismatched HSCT.

Survival after HSCT for SCID has improved over the years,² reflecting more effective treatment and prevention of disease-related and transplantation-associated complications, such as infections and GvHD. In particular, current survival rate after HSCT from HLA-identical related donors is over 90%, whereas survival after HSCT from related HLA-mismatched donors has improved from 35% in transplants performed up to 1985 to 75% in those performed between 1996 and 1999.²

Several factors influence survival after HSCT for SCID. In particular, younger age at transplantation leads to superior survival. Among 38 infants who were treated by Buckley and collaborators before 3.5 months of age, 37 (97%) have survived.^{3,6,19} Importantly, the vast majority of these infants received T cell-depleted HLA-mismatched HSCT from a parent, without any conditioning or GvHD prophylaxis. In Europe, among infants with SCID who received HLA-identical transplantation, survival was clearly better when HSCT was performed at less than 6 months of age (85% survival rate) than at 12 months or more (survival rate 53%).²

Fig. 83.2 Kaplan-Meier survival curve in 25 infants with B⁺ SCID and 16 infants with B⁻ SCID, treated by mismatched related HSCT at the authors' institution.

Other factors that result in increased survival include the use of prophylactic co-trimoxazole for recipients of HLA-identical HSCT; isolation in a protected environment; and lack of pre-transplant pulmonary infection among recipients of related HLA-mismatched HSCT.²

Survival following related HLA-mismatched HSCT is better in infants with B⁺ SCID than with B⁻ SCID (64% vs 36%, respectively).² The poorer outcome observed in infants with B⁻ SCID may reflect the presence of autologous NK cells detectable in most of these infants, as well as a higher rate of severe post-transplant complications. Also, at the authors' institution, among 41 infants with SCID treated by haploidentical HSCT, survival was better for infants with B⁺ SCID (59.3%) than in those with B⁻ SCID (survival rate 40%) (Fig. 83.2).

Recently, HSCT from MUD has been shown to be an effective treatment for SCID. In a series of 41 patients treated with MUD HSCT at two centers (the authors' institution, and the Hospital for Sick Children, Toronto), 33 (80%) have survived, compared to a 92% survival rate among 13 recipients of related HLA-identical HSCT, and 52% survival among 40 patients treated by related T cell-depleted HLA-mismatched transplantation.⁸ Furthermore, in this study the use of MUD HSCT was reported to lead to sustained engraftment and better immune reconstitution than with T cell-depleted haploidentical HSCT. These favorable data have been confirmed by a smaller series of transplants performed at a single center in Japan, in which all seven recipients of MUD HSCT were reported to be alive, compared to only one of eight patients treated by T cell-depleted haploidentical HSCT.⁹

Complications following HSCT for SCID

In spite of advances in prophylaxis and treatment, infections (especially those caused by viruses) remain the major complication observed after HSCT for SCID. In a report of 132 transplants performed at their center, Buckley and collaborators¹⁹ indicate that viral infections accounted for 24 of the 30 deaths observed. CMV and adenovirus were responsible for seven deaths each, and 10 additional deaths were due to infections caused by EBV, enteroviruses, varicella, and herpes simplex.

Similarly, a large European study reports that 56% of all deaths were due to infections, 25% to GvHD, and 5% to BLPD.² In another study focusing on long-term outcome in 193 SCID patients treated in Europe by T cell-depleted mismatched HSCT, Haddad et al.²⁰ reported that of

116 patients who were alive 6 months after HSCT, 24 (20%) later died, most commonly in the first 2 years. Viral infections and/or GvHD accounted for 18 of these late deaths. Importantly, persistence of poor T-cell function 12 months after HSCT was the major determinant of negative outcome. In the same paper, other causes of late death included immune dysfunction and severe autoimmunity.

At the authors' institution, out of 69 SCID infants treated by HSCT, 20 (29%) have died. Of these, 12 developed a fatal viral infection that most often caused interstitial pneumonia (nine cases) or encephalitis (two patients). Other causes of death were GvHD (two patients), severe autoimmune hemolytic anemia (three patients), and BLPD, MOF, and encephalopathy of unknown origin (one case each).

As mentioned above, in all of these studies mortality was higher among recipients of T cell-depleted mismatched HSCT than in related or unrelated HLA-identical transplantation. In particular, the higher incidence of viral infections in the first group of patients reflects the delayed T-cell reconstitution observed following T cell-depleted mismatched HSCT.

Chronic skin warts, due to papillomavirus infection, have been observed after HSCT in infants with γ c or JAK3 deficiency.²¹ This complication may reflect the lower number of NK cells detectable after HSCT in infants with NK⁻ SCID; alternatively, chronic papillomavirus infection might result from genetically determined signaling defects that are not restricted to the lymphoid system but also involve skin cell types such as keratinocytes.

GvHD is another major complication of HSCT for SCID. Buckley¹⁹ reported that GvHD occurred in 40/117 (34%) patients given T cell-depleted mismatched parental bone marrow, six of 15 (40%) given unfractionated HLA-identical marrow, and four of five given placental blood. In most cases, GvHD occurred when transplacentally acquired T lymphocytes were present. Most GvHD observed was mild (grade I or II) and required no treatment. Eleven patients developed grade III or IV GvHD, which was treated with steroids, cyclosporine, and/or tacrolimus. None of these patients have died, but one has developed cGvHD.

In their series of 475 SCID patients transplanted in Europe, Antoine et al.² reported that GvHD accounted for 25% of all deaths. In particular, the occurrence of aGvHD led to poorer survival in patients treated by T cell-depleted related mismatched transplantation (52% survival rate vs 77% among those infants who did not develop aGvHD). On the other hand, in this type of transplant there has been a continuous decrease in the incidence of aGvHD over the years, from 35–40% before 1996 to 22% thereafter.

In their recent article describing experience of HSCT for SCID at two centers (Brescia, Italy; and Toronto, Canada), Grunebaum et al.⁸ reported that aGvHD developed in four of 13 patients (31%) who received related HLA-identical HSCT, 18 of 40 (45%) patients treated by T cell-depleted haploidentical transplantation, and 30 of 41 (73%) of patients receiving MUD HSCT. Thus, unfractionated HSCT from MUD appears to increase the risk of aGvHD, possibly reflecting mismatch at minor histocompatibility loci. In spite of this difference, the incidence of aGvHD grade III or IV was similar (15–22%) among recipients of T cell-depleted mismatched HSCT or of MUD HSCT. Although continuous improvements in HLA typing have resulted in a progressively lower incidence of GvHD, these data illustrate the need for careful monitoring of infants treated with other than related HLA-identical HSCT, and call for adherence to guidelines on the use of immunosuppression for GvHD prophylaxis after MUD HSCT or after conditioned T cell-depleted haploidentical transplantation.

Fig. 83.3 Mean (\pm SE) numbers of CD3⁺ T cells, CD19⁺ B cells, and CD16⁺ natural killer cells (**A**) before transplantation and (**B**) at the most recent evaluation after transplantation performed at the authors' institution, according to the type of SCID.

Immune dysregulation and autoimmunity represent additional complications of HSCT for SCID. In a joint series of 94 infants with SCID transplanted in Brescia and Toronto, we have reported that six of 41 patients who received MUD HSCT, and five of 40 children treated by T cell-depleted haploidentical transplantation developed autoimmune cytopenias.⁸ These complications may develop a few months after HSCT (when skewing of the T-cell repertoire may be observed), or may persist, particularly in infants with delayed and incomplete immune reconstitution. Autoimmunity after HSCT may also be part of cGvHD.

Quality and kinetics of T-cell immune reconstitution

The effectiveness of HSCT in SCID is well illustrated by the normalization of the number and function of T lymphocytes achieved after transplantation (Figs 83.3 and 83.4). The efficacy of the procedure has been demonstrated in all forms of SCID, although T-lymphocyte counts after HSCT tend to be lower in patients with adenosine deaminase (ADA) deficiency, possibly reflecting irreversible thymic damage. Moreover, normalization of the T-lymphocyte count after HSCT demonstrates the ability of the stem cells to seed and differentiate in a vestigial thymus.

The kinetics of T-lymphocyte reconstitution differs substantially depending on the type of transplantation. The unmanipulated graft from a related HLA-identical donor contains mature T lymphocytes. Homeostatic as well as antigen-driven expansion of these mature

T cells occurs as early as 2 weeks after transplantation (Fig. 83.5).^{19,22} These T cells tend to be oligoclonal, have a memory (CD45R0) phenotype, are fully competent, and in fact provide the recipient with functional immunity.²³

Mature T cells are present also in the graft collected from MUDs. However, the use of a conditioning regimen in MUD HSCT at least partly impairs immune development in such transplants, compared to unconditioned HSCT from related HLA-identical donors (Fig. 83.5). In contrast, newly generated naïve (CD45RA⁺ CD31⁺) T lymphocytes do not appear in the circulation until 3–4 months after HSCT, irrespective of the type of transplant (HLA identical or mismatched), and their number tends to peak approximately 1 year after HSCT, when a fully polyclonal T-cell repertoire is usually observed.²³ These naïve T lymphocytes are the product of ongoing active thymopoiesis, as shown by the fact that they contain T-cell receptor excision circles (TRECs). TRECs are extrachromosomal DNA episomes that are generated during V(D)J recombination, and are not duplicated during mitosis. Therefore, TRECs identify newly generated naïve T lymphocytes.

The kinetics of T-cell reconstitution is influenced by the recipient's age. Transplants performed early in life (<3.5 months of age) lead to superior thymic output.⁶ This may reflect lack of thymic damage (which in contrast is often observed after infections); alternatively, it is possible that a younger thymus has an intrinsically superior ability to support active thymopoiesis.

Fig. 83.4 Number of TRECs (**A**) and *in vitro* proliferative response to phytohemagglutinin (PHA) (**B**) before transplantation and at the last follow-up after transplantation in a series of 42 SCID infants treated at the authors' institution, according to the type of SCID.

Fig. 83.5 Kinetics of CD3⁺ T lymphocytes reconstitution in 48 SCID infants following HLA-identical ($n=12$), MUD ($n=15$) or haploidentical ($n=21$) HSCT, performed at the authors' institution. Geometric mean CD3⁺ T-cell counts are shown.

Quantification of TRECs sequentially after HSCT is a solid approach to assess engraftment of bona fide stem cells and to monitor the persistence of immunity. It has been shown that levels of TRECs tend to decline by 10 years after unconditioned HSCT,²⁴ when oligoclonal representation of the T-cell repertoire appears, particularly within CD8 T lymphocytes.²³ This decline of thymic function in SCID recipients of HSCT is more rapid than what is observed in normal children. The reasons for this difference are not clear. It is possible that the SCID thymus is not able to sustain active thymopoiesis for as long as a normal thymus. Alternatively, a low dose of infused stem cells, HLA incompatibility between donor and recipient, and GvHD may also contribute to the observed accelerated thymic involution after HSCT. Even if it is not necessary to provide T-cell reconstitution in SCID, the prior use of chemotherapy might facilitate engraftment of stem cells and thus sustain long-term immune reconstitution. However, no studies have compared long-term thymopoiesis in myeloablated MUD HSCT versus unconditioned related HLA-identical HSCT.

In any case, this late decline of T cell-mediated immunity after HSCT is not negligible. Data from the European registry indicate that at the time of last follow-up as many as 16% of recipients of HLA-identical HSCT and 18% of recipients of haploidentical HSCT had a T-cell immunodeficiency (defined as fewer than 1000 T lymphocytes/ μ L).²

Reconstitution of B- and NK-cell immunity

In contrast to what was observed for T lymphocytes, the engraftment of B cells after HSCT for SCID is often problematic and may require 2 years or more to develop.³ In their series, Buckley and colleagues¹⁹ report that only six of 12 recipients of HLA-identical bone marrow, and 21 of 76 patients treated by unconditioned T cell-depleted haploidentical transplant had evidence of donor-derived B lymphocytes; overall, 62 of 102 survivors were requiring intravenous immunoglobulins. Booster transplants have been used to overcome these problems; 21 of 33 patients who received such boosters at Buckley's institution were reported to be alive, and most of them normalized or improved their immune function.³ In Europe, the use of pre-transplant conditioning regimens has been advocated in haploidentical HSCT with the goal of facilitating engraftment of stem cells and hence also of B lymphocytes. Among 28 infants with B⁺ SCID treated by HSCT at the authors' institution, all those ($n=11$) who did not receive conditioning failed to achieve engraftment of donor B cells; on the other hand, 12 of 17 of those who received pre-transplant chemotherapy had evidence of B-cell engraftment.

The use of a conditioning regimen is particularly important to achieve B-cell function in patients with B⁻ SCID treated by haploidentical HSCT. In a report from the European series, none of the patients with B⁻ SCID who received unconditioned haploidentical HSCT developed normal B-cell function.²⁰ In patients with B⁺ SCID, the difficulty of achieving B-cell engraftment after unconditioned HLA-identical HSCT may reflect competition between host and donor early B-cell precursors.²⁵

Finally, attainment of a normal B-cell function may also depend on the nature of the genetic defect, as shown by the fact that among infants with B⁺ SCID, those who have an *IL7RA* gene defect usually develop normal B-cell immunity after HSCT even if no donor-derived B cells are present, whereas patients with γ c or JAK3 deficiency (both of which compromise B-cell function) often remain dependent on immunoglobulin substitution therapy if engraftment of donor-derived B cells is not achieved.²²

More limited data are available about reconstitution of NK cell function. In patients with NK⁻ SCID, NK are often the first cells to appear after haploidentical HSCT.³ Lower NK cell counts have been reported at long-term follow-up after HSCT in patients who originally had an NK⁻ form of SCID (such as γ c or JAK3 defects).^{19,22} Whether this may contribute to the occurrence of papillomavirus infection in patients transplanted because of γ c or JAK3 defects remains unknown.

HSCT FOR IMMUNODEFICIENCIES OTHER THAN SCID

Immunodeficiencies other than SCID are characterized by residual T cell-mediated immunity that may prove an obstacle to engraftment of donor-derived stem cells. For this reason, a pre-transplant conditioning regimen is required to treat these disorders, even when an HLA-identical donor is available. Furthermore, results of T cell-depleted haploidentical transplant are not particularly good in these diseases. This has prompted the use of HSCT from alternative donors (MUDs and cord blood).

Although these disorders may be severe, they rarely represent a medical emergency and often permit longer survival. Consequently, the decision whether to attempt HSCT for immunodeficiencies other than SCID must be based on a careful evaluation of the patient's clinical history and quality of life, the effectiveness of alternative and more conservative approaches, as well as on current knowledge of the clinical

course for that specific disorder and of genotype–phenotype correlation, if known. In many cases, this remains a difficult decision, which must be shared between the physician and the family (and the child, when possible). On the other hand, advances in critical and supportive care, and improved availability of alternative donors, have resulted in more effective application of HSCT even for this difficult set of patients.^{2,3} At the authors' institution, 79 patients with immunodeficiency other than SCID have received HSCT. Of these, 23 were treated by related HLA-identical transplant, 13 by T cell-depleted haploidentical HSCT, and 43 by MUD HSCT. The overall survival rates were 78.5%, 53.8%, and 78.1%, respectively (Fig. 83.1B).

Combined immunodeficiencies other than SCID

Omenn's syndrome is a fatal disorder unless treated with HSCT. In the past, satisfactory results had been obtained with transplantation from related HLA-identical donors (with a survival rate of 75%), whereas other types transplantation had led to poorer outcome (41% survival after haploidentical transplant, and 50% after MUD HSCT).³ More recent data, however, indicate a lower mortality. Nine of 11 patients with Omenn's syndrome transplanted at the authors' institution are alive; importantly, of these, only one had a matched sibling, whereas two infants had a phenotypically identical related donor, three were treated by MUD HSCT, and five received a haploidentical HSCT.²⁶

HSCT has been attempted also in other predominant T-cell immunodeficiencies, such as purine nucleoside phosphorylase deficiency, cartilage–hair hypoplasia, and other forms of T-cell activation deficiency, with an overall survival rate of approximately 50%.³

Major histocompatibility complex (MHC) class II deficiency remains a very difficult disease to transplant, with 54% survival rate after HLA-identical HSCT,³ and only 32% 1-year survival after haploidentical transplant.² Possibly, the persistent lack of expression of HLA class II molecules on thymic epithelium may cause failure to attain a normal CD4 T-cell count after transplant.

HSCT for DiGeorge syndrome may be attempted only when an HLA-identical donor is available; in such cases, immune reconstitution is provided by T lymphocytes contained in the graft.²⁷

Patients with CD40 ligand (CD40L) deficiency suffer from recurrent bacterial and opportunistic (*Pneumocystis jiroveci*, *Cryptosporidium parvum*) infections, resulting in a survival rate of only 46% at 25 years of age according to the European Registry (Notarangelo, unpublished). Consequently, HSCT has been advocated as the treatment of choice for this disease. In a series of 38 patients transplanted in Europe, 26 (68.4%) survived.²⁸ Early age at transplantation and lack of pre-existing pulmonary disease were associated with a more favorable outcome.

Finally, we have recently obtained the first evidence of successful HSCT in a child with CD40 deficiency who has received bone marrow from her HLA-identical sibling.⁴⁹

Pre-existing viral infections and/or organ damage (possibly related to the conditioning regimen) are responsible for most deaths in patients with combined immunodeficiency other than SCID. As an attempt to reduce drug-related toxicity, several groups have used reduced-intensity conditioning. Nineteen of 21 patients with various immunodeficiencies treated by HSCT with a nonmyeloablative regimen were reported to be alive at a median follow-up of 13 months.²⁹ However, nonmyeloablative conditioning does not always allow for sustained engraftment of donor stem cells, so that repeated transplants are often necessary.

Wiskott–Aldrich syndrome

Bone marrow transplantation for correction of WAS was attempted as early as 1968, with partial success.¹⁸ Full correction following HSCT was first reported in 1978, when a more robust conditioning regimen was used.³⁰ Since then, results of related HLA-identical HSCT in WAS have been consistently good; in contrast, poorer results have been achieved with T cell-depleted haploidentical transplants. In a survey of the International Bone Marrow Transplant Registry of 170 WAS patients treated with HSCT, the survival rate was 87%, 52%, and 71% for HLA-identical, haploidentical, and MUD transplants, respectively.³¹ In this study, MUD HSCT was effective especially in children less than 5 years of age. In Europe, out of 75 patients treated by HLA-identical or haploidentical transplantation, survival rates were 81% and 43%, respectively.² Overall, these studies indicate that indications for haploidentical HSCT should be carefully reviewed, and possibly restricted to severely affected patients for whom no alternative donors have been identified.

Recent data support the efficacy of MUD HSCT for WAS. At the authors' institution, 23 WAS patients were transplanted, 16 of whom received MUD HSCT. Overall survival was 78.2%; specifically, survival among recipients of MUD HSCT was 81.2%.

Finally, cord blood transplantation has been increasingly reported as an effective form of treatment for WAS.³²

Effective prevention and treatment of EBV-related BLPD (a common complication of HSCT in WAS) has been essential to the improved outcome of HSCT for WAS.

Cytotoxicity defects

Familial hemophagocytic lymphohistiocytosis (FHL) comprises a genetically heterogeneous group of disorders of T- and NK cell-mediated cytotoxicity. Although chemotherapy may induce remission, patients with FHL tend to relapse and ultimately die, mostly due to MOF observed in the accelerated phase of the disease. At present, HSCT is the only curative approach to FHL.³³ In an international study on 86 children with FHL who received chemotherapy followed by HSCT, the overall 3-year survival after HSCT was 64%. Survival was similar for related HLA-identical (71%) and MUD (70%) transplantation, but was less good (survival rate 50%) with a mismatched related donor.³³ Also in the European experience, 3-year survival was better for HSCT from genotypically identical than from HLA-mismatched related donors (68% vs 49%, respectively).² A single-center report of 48 patients transplanted at Hôpital Necker, France, gave an overall survival of 58.5%, and transplants from related HLA-identical or MUD gave a better outcome than from mismatched related donors.³⁴ Importantly, a stable donor chimerism $\geq 20\%$ is sufficient to provide long-term remission. Accelerated disease is the major risk factor for failure of HSCT and death.^{33, 34} Furthermore, VOD and pulmonary hypertension have frequently been observed after HSCT for FHL.

The selection of optimal family donors is an important issue for HSCT in FHL. Because of the lack of reliable assays (other than genetic analysis, when possible) to identify affected individuals at a pre-symptomatic stage, transplant from siblings carries the risk of using an affected individual as a donor. For this reason, whenever the molecular defect in the family is known, genetic testing is strongly recommended before HSCT from a sibling is attempted.

Chediak–Higashi syndrome (CHS) can be cured by bone marrow transplantation;³⁵ also for this disease, better results have been obtained with HSCT from HLA-identical siblings or MUDs. At the authors' institution, three patients with CHS have been treated and all are alive and in full remission. On the other hand, the long-term outcome of CHS patients treated with HSCT remains unclear, especially as neurological deterioration has been consistently observed several years after transplant.³⁶

HSCT has been also shown to be curative for X-linked lymphoproliferative disease (XLP).^{3, 10} Ideally, the transplant should be performed before EBV infection.

Phagocytic cell disorders

Although regular administration of prophylactic antibiotics and antifungals (with or without interferon- γ) has clearly improved the outcome in patients with CGD, this remains a severe disorder, with a rather high risk of complications and death. Therefore, there has been a renewed interest in HSCT for CGD. In a survey of the European experience from 1985 to 2000, 27 patients with CGD were treated by HSCT; most of them received unmodified bone marrow from an HLA-identical sibling after myeloablative conditioning. Overall, 23 of 27 patients were reported to be alive, and the disease had been cured in 22 of them.¹⁴ In this study, all 18 patients who were infection free at the time of transplantation survived. Based on these data, HSCT early in life appears to be a safe and effective form of treatment for CGD patients who have a matched sibling.

HSCT is a successful and life-saving procedure also in patients with the complete form of leukocyte adhesion deficiency type 1 (LAD1), even when performed from MUD or related mismatched donors.³⁵ Recently, HSCT with reduced-intensity conditioning, allowing stable mixed chimerism, has been successfully used in such patients.³⁷

Administration of recombinant G-CSF is the treatment of choice for patients with severe congenital neutropenia (SCN). However, a subgroup of these patients fail to respond to G-CSF, and some of these are at high risk for the development of myelogenous leukemia. Data from the SCN International Registry reported that from 1976 to 1998 11 SCN patients were treated with HSCT for reasons other than malignant transformation.³⁸ Of these, seven of eight who had a matched sibling survived with engraftment, and one rejected and had autologous reconstitution. Of the three patients treated by mismatched transplantation, two died and one developed very severe GvHD. Data from the French SCN Registry indicate that nine patients were transplanted (seven from a MUD and two from a matched sibling). Engraftment occurred in all but one of the patients. Three died, and six are alive in complete remission.³⁹ Two patients with SCN refractory to treatment with G-CSF have been successfully transplanted from a MUD at the authors' institution.

Other primary immunodeficiencies

Interferon- γ receptor 1 deficiency leads to severe mycobacterial infections, with a high mortality rate early in life. Although HSCT should theoretically correct the disease, with few exceptions the results have been very disappointing. In particular, an international survey on eight patients transplanted showed that only two were in full remission 5 years later.⁴⁰ These are the only two who had received HSCT from an HLA-identical sibling after full myeloablative conditioning. The reasons for the unsatisfactory application of HSCT in this disease remain unclear.

Immunodysregulation, polyendocrinopathy, enteropathy, X-linked (IPEX) syndrome often leads to early death. In spite of the fact that partial engraftment after stem cell transplantation in the murine model of the disease is able to induce sustained remission, the experience with HSCT in IPEX patients has not been very successful.⁴¹ We have been able to achieve sustained remission with stable mixed chimerism following HSCT from a matched sibling in one case of IPEX.⁴²

Autoimmune lymphoproliferative syndrome (ALPS) is usually treated by immune suppression, and possibly by splenectomy. However, a successful outcome of HSCT has been reported in a few patients with severe ALPS.^{43,44}

PERSPECTIVES FOR HSCT IN THE TREATMENT OF PRIMARY IMMUNODEFICIENCIES

Although HSCT has clearly shown its efficacy in patients with severe forms of primary immunodeficiency, several goals remain to be met. In particular, the main areas of interest for future development include methods to improve and sustain engraftment of stem cells; strategies to facilitate engraftment and to reduce the incidence of GvHD in recipients of mismatched or matched unrelated transplants; attempts to improve thymopoiesis, with the aim of accelerating immune reconstitution and avoiding or postponing long-term decline of immunity; and amelioration of strategies aiming at reducing the burden of infections after HSCT.

Strategies aimed at improving thymic function after HSCT (reviewed in⁴⁵) may include protection of thymic stroma that supports thymopoiesis; and direct stimulation of early T-cell progenitors. Keratinocyte growth factor (KGF) is potentially attractive because it protects the thymic stroma. Administration of KGF before HSCT has been shown to enhance thymopoiesis and peripheral T-cell numbers, and to reduce the incidence and severity of GvHD in murine models of HSCT.⁴⁵ However, more must be learned on the long-term outcome of this treatment before clinical trials can be started.

Recently, a common thymic epithelial precursor for all thymic epithelial cells has been identified in mice.⁴⁶ This precursor cell may give rise to a functional thymus *in vivo*. Should a similar element be identified in humans, it might prompt novel strategies aimed at accelerating T-cell recovery after HSCT.

Attempts to accelerate immune reconstitution might be based on the use of cytokines that promote T-cell development and maturation in the thymus, such as IL-7. However, experience in severely immunodeficient mice has shown that infusion of IL-7 provides limited benefit in the MHC-compatible or partially compatible setting, whereas in a fully mismatched setting it has facilitated T-cell development.⁴⁷

Infusion of donor T cells that have anti-infective activity but no GvHD activity might help reduce infection-related mortality after HSCT. Such strategy could be based on removal of alloreactive cells by negative selection using anti-CD25 or anti-CD69 antibodies.

Recognition that B-cell engraftment after HSCT is hampered by competition between host and donor early B-cell precursors²⁵ may

CLINICAL PEARLS

OUTCOME OF STEM CELL TRANSPLANTATION FOR PRIMARY IMMUNODEFICIENCIES

- >> For SCID, the overall survival rate of patients transplanted since 1968 is over 70%, and is higher for patients treated by HLA-identical transplantation.
- >> There has been a continuous improvement in the outcome of the procedure.
- >> Survival rates are over 90% for HLA-identical transplantation, and 75% for haploidentical transplantation for SCID.
- >> Improvement in clinical care (both in critical care and in prevention/treatment of infections) has recently led to exploit efficacy of MUD transplantation also for SCID, with excellent results.
- >> The decision to attempt a MUD transplantation for SCID must be weighed against the risks associated with the time interval required to identify such a donor.
- >> Factors influencing survival after transplantation for SCID include younger age at transplant, prevention of GvHD, and control of infections. For the latter, isolation in a protected environment, and prophylactic use of antibiotics are effective measures.
- >> The decline of T-cell function that is observed at 10 years or more after unconditioned transplantation remains a concern, and may cause clinical problems. Therefore, there is a need for improvements in the procedures used to facilitate and sustain stem cell engraftment, and/or to boost donor-derived immunity.
- >> For primary immunodeficiencies other than SCID, there has been a progressive improvement in the outcome following stem cell transplantation.
- >> Results are good both for HLA-identical transplants (with a survival rate of 70% or more, depending on the disease), and for MUD or cord blood transplantations.
- >> Reduced-intensity conditioning regimens have been often used in these patients, in the attempt to reduce the risks of drug-related toxicity.

prompt novel forms of conditioning regimen targeted to host pro-B lymphocytes, with the aim of facilitating the development of donor-derived B cells, even in the HLA-identical setting.

Finally, it has recently been demonstrated in a murine model that endogenous stem cells obstruct the engraftment of donor-derived stem cells, and that the recipient's CD4 T lymphocytes inhibit productive engraftment, possibly by recognizing subtle histocompatibility differences.⁴⁸ Novel strategies aimed at interfering more specifically with the mechanisms involved in graft rejection, without requiring full myeloablation, could therefore be envisaged, at least for some severe T-cell immunodeficiency disorders.

Thymic reconstitution

M. Louise Markert, Blythe H. Devlin

84

INTRODUCTION

Thymus transplantation is a promising experimental procedure for reconstitution of thymic function in patients with congenital athymia. Thymus transplantation was initiated in the 1960s and 1970s as a means of reconstituting the T-cell population and function in infants who presented with infections and low T-cell numbers. Although there were some reports of success, most patients died.¹ The poor results at that time may have been secondary to the difficulty in distinguishing athymic patients from those with a genetic defect in bone marrow stem cells. In addition, at the time, reagents such as monoclonal antibodies reactive with thymic epithelium were not available to evaluate the quality of thymus tissue. In the 1990s, with the ability to identify appropriate patients for treatment and with better reagents for assessing graft quality, the feasibility of using thymus transplantation was readdressed.

A summary of results of thymus transplantation by the authors is presented. The clinical trials involve patients with complete DiGeorge anomaly. With follow-up times of up to 12 years, the safety profile and resulting T-cell function are excellent.^{2,3} The transplant recipients continue to be followed to assess the persistence of T-cell numbers and function and to monitor for potential autoimmune disorders. These studies are performed under an Investigational New Drug (IND) application with the Food and Drug Administration.

PATIENT POPULATIONS

Patients who may benefit from thymus transplantation include infants with congenital athymia from complete DiGeorge anomaly. This is a heterogeneous congenital anomaly in which infants present with variable defects in the heart, parathyroid gland and thymus.⁴⁻⁷ Of these, fewer than 1 in 200 have athymia and thus are categorized as having 'complete' DiGeorge anomaly.⁸ Based on 48 infants with complete DiGeorge anomaly enrolled in transplantation protocols, 39 of whom received thymic transplants, the main genetic and syndromic risk factors for complete DiGeorge anomaly include 22q11 hemizygosity, CHARGE (coloboma, heart anomaly, choanal atresia, retardation, and genital and ear

anomalies) association and diabetic embryopathy (Table 84.1).⁹⁻¹¹ It is notable that less than half of infants with complete DiGeorge anomaly are hemizygous at chromosome 22q11. All athymic patients present at birth with very low T-cell counts ($<50/\text{mm}^3$). They are consequently profoundly immunodeficient and susceptible to infections.

Athymic infants with complete DiGeorge anomaly can develop oligoclonal T-cell populations at varying times after birth, usually within the first 12 months of life. The oligoclonal T cells can infiltrate the skin and other organs. Figure 84.1 panel A shows a typical rash associated with circulating oligoclonal T cells. The rash is similar to severe atopic dermatitis or graft-versus-host disease. On biopsy, the rash appears to be spongiotic dermatitis with T-cell infiltration.¹² Lymphadenopathy develops subsequent to the rash. Upon biopsy, the lymph nodes are typically given the diagnosis of dermatopathic lymphadenopathy. The term atypical complete DiGeorge anomaly is used to characterize these patients. Athymic infants who develop circulating oligoclonal T cells remain susceptible to infections.

DIAGNOSIS OF ATHYMIA

Infants that may benefit from thymic transplantation require prompt diagnosis of athymia for effective treatment. The absence of a typical thymic shadow on chest X-ray, CT scan, or magnetic resonance imaging (MRI) cannot be used to diagnose athymia. The thymus may be embedded in the thyroid, for instance (unpublished findings). A small mass in the location where one anticipates finding the thymus may be a lymph node instead. Therefore, one must rely on blood tests to assess thymic function.

In normal infants, thymic function is revealed by the presence in blood of recent thymic emigrants, also called 'naïve T cells.' All T cells express the CD3 proteins, but naïve T cells also express the cell surface proteins CD45RA and CD62L.¹³ The co-expression of these molecules can be assessed by flow cytometry. Over 50% of a normal infant's T cells are naïve, reflecting active thymic function. Another characteristic of good thymic function is the presence of a broad T-cell receptor repertoire in the blood. The assays to assess these characteristics and the interpretation of the data in the differential diagnosis of athymia in infants with DiGeorge syndrome are described below in greater detail.

In typical complete DiGeorge anomaly, the total number of T cells (and hence the number of naive T cells) is usually $<50/\text{mm}^3$ and thus thymic function is considered to be absent. These T-cell numbers are profoundly depressed compared to a normal infant's T-cell count of $>2000/\text{mm}^3$, with over 50% being naive. The evaluation of thymic function is more difficult in patients with atypical complete DiGeorge anomaly because proliferation of the oligoclonal T cells may lead to significantly elevated T-cell numbers.^{3, 12} The lack of thymic function in

these infants is demonstrated when less than 5% of total T cells are found to be naive by flow cytometry. Figure 84.2 presents an example of an infant with fewer than 5% naive T cells prior to transplantation when the T-cell count was $2113/\text{mm}^3$. The very low percentage ($<5\%$) of T cells co-expressing the markers CD45RA and CD62L confirms the diagnosis of athymia. It should be noted that the oligoclonal T cells present in athymic patients may proliferate in response to the mitogen phytohemagglutinin (PHA). Thus, a T-cell proliferative response to mitogens such as PHA cannot be used to confirm the presence of a thymus.^{3, 12} The oligoclonal T cells that respond to PHA in patients with atypical complete DiGeorge anomaly do not protect against pathogens, and the patient remains susceptible to infections.

Table 84.1 Syndromic associations in complete DiGeorge anomaly

Genetic or syndromic associations	Percentage*
22q11 hemizygosity	46
CHARGE	25
Infant of diabetic mother	21
Ectodermal dysplasia	2
None	6

CLINICAL PEARLS

Perform a T-cell count to diagnosis complete DiGeorge anomaly in all infants with the following:

- >> 22q11 hemizygosity
- >> CHARGE
- >> Primary hypoparathyroidism
- >> Truncus arteriosus
- >> Interrupted aortic arch type B

Fig. 84.1 Dermatologic findings in patient with atypical complete DiGeorge anomaly. (A) Rash before and (B) skin after thymus transplantation. Note hair loss with rash and regrowth after thymus transplantation.

A broad T-cell receptor (TCR) repertoire is found in infants with normal thymic function. Circulating T cells in athymic infants are usually oligoclonal. To support the diagnosis of athymia in patients who have circulating T cells, diversity of the TCR repertoire is evaluated by spectratyping. Spectratyping assesses the repertoire of the TCR β chain variable segment (TCRBV) usage.^{2,3} Most T cells express the TCR $\alpha\beta$ receptor. Spectratyping uses PCR to amplify the TCRBV-containing mRNAs for different TCRBV families. In a normal individual with a

CLINICAL PEARLS

Although the chest X-ray, CT scan or MRI scan can be used to detect the lack of a thymus gland in an infant suspected of the DiGeorge anomaly, immune tests of the blood cells are necessary to confirm the diagnosis. These tests include measurements of total (CD3) T cells and naïve (CD45RA⁺CD62⁺) T cells by flow cytometry and assessment of the T-cell receptor β chain variable segment (TCRBV) repertoire by spectratyping.

KEY CONCEPTS

CHARACTERISTICS OF NAIVE T CELLS

- Co-expression of CD45RA and CD62L
- Broad T-cell receptor repertoire

Fig. 84.2 Naïve CD45RA⁺CD62L⁺ T cells pre and post thymus transplantation. **(A)** Naïve CD3 T cells (1%) on day -8 pre thymus transplantation and **(B)** naïve CD4 T cells (69%) on day 550 (year 1.5) post transplantation in a patient with atypical complete DiGeorge anomaly. This is the same patient whose data are illustrated in Figure 84.6, panels D–F. On day -8 pre transplantation, the patient had 7684/mm³ total T cells with 585/mm³ CD4 T cells, 4594/mm³ CD8 T cells and 2506/mm³ double-negative T cells. On day 550 post transplantation the patient had 1013/mm³ T cells with 674/mm³ CD4 T cells, 251/mm³ CD8 T cells, and 82/mm³ double-negative T cells.

diverse TCRBV repertoire, a quasi-gaussian distribution of lengths of the mRNAs utilizing each TCRBV segment is present because of the variability of recombination joints between the variable (V), diversity (D), and joining (J) gene segments in the chromosome. Different forward primers specific for the various TCRBV-variable regions are used to amplify cDNA in separate reactions with a single reverse primer that hybridizes with either of the two TCRBV constant regions. The PCR products are end-labeled and size-separated by electrophoresis or capillary gels. Figure 84.3 panel A presents a spectratype from a patient with atypical complete DiGeorge anomaly who has an oligoclonal repertoire. Panel B illustrates a normal quasi-gaussian spectratype from a patient with typical complete DiGeorge anomaly 4.5 years after thymus transplantation. When a patient with DiGeorge anomaly has normal numbers of T cells and very few naïve T cells, as in Figure 84.2, the TCRBV repertoire will be oligoclonal as in Figure 84.3 panel A. This association of oligoclonality with low naïve T-cell numbers is related to the loss of CD45RA and the acquisition of CD45RO as T cells proliferate. All patients with atypical complete DiGeorge anomaly who have a very low percentage of naïve T cells have had an oligoclonal TCRBV repertoire.

THYMUS TRANSPLANTATION

PREPARATION OF THYMUS TISSUE FOR TRANSPLANTATION

Thymus tissue is often removed by pediatric cardiac surgeons in order to access the surgical field necessary to repair the heart. For thymus transplantation, informed consent is obtained from the parents of the infant undergoing heart surgery in order to collect discarded tissue. The thymus is collected aseptically and processed in the laboratory. Based on the procedures initially described by Hong,¹⁴ the thymus is sectioned and the slices are maintained in tissue culture for 2–3 weeks. Donor screening includes testing and screening for risk factors as recommended for all cell and tissue products (Code of Federal Regulations Title 21; Part 1270). HLA matching is not required, but the HLA types of the donor and recipient are evaluated.

USE OF IMMUNOSUPPRESSION

Table 84.2 shows the number of patients who were transplanted without immunosuppression and the number given immunosuppression. No immunosuppression was used in 21 patients with typical complete DiGeorge anomaly who had very low T-cell numbers and very depressed T-cell proliferative responses to the mitogen PHA, as these patients cannot reject transplants.² Another 18 patients were immunosuppressed with deoxycoryformycin (one patient) or pre-transplant rabbit anti-thymocyte globulin (17 patients).^{3,12} Of the group of 17 treated with anti-thymocyte globulin, peri-transplantation cyclosporine was used in six. Peri-transplantation steroids were used in five of these plus one other, who did not receive cyclosporine. Infections and deaths did not increase in the infants who received immunosuppression compared to those who did not.

Immunosuppression is given if an infant has atypical complete DiGeorge anomaly, or if there is an elevation in the T-cell responses to mitogens in patients with typical complete DiGeorge anomaly. The

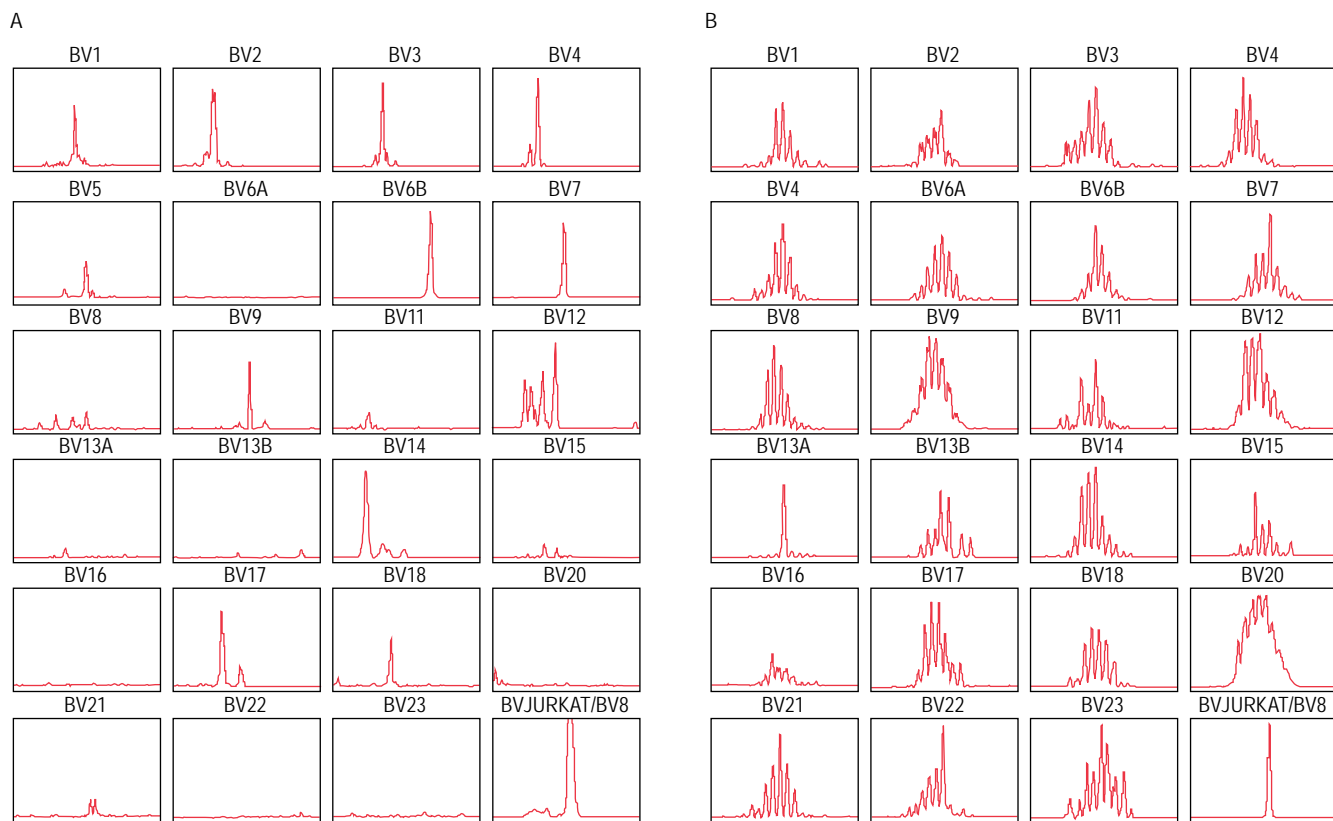

Fig. 84.3 Spectratype evaluation of TCRBV repertoire. **(A)** An oligoclonal CD4 spectratype from an infant with atypical complete DiGeorge anomaly who had 5897/mm³ circulating T cells with 2726/mm³ CD4 T cells. **(B)** Post transplantation CD4 T cell immunoscope in a patient with typical complete DiGeorge anomaly 4.5 years after transplantation, when the T-cell count was 998/mm³ with 729/mm³ CD4 T cells. The TCRBV family designation is above each panel. The Jurkat/TCRBV 8 control is in the bottom right panel of each spectratype. These spectratypes contrast the oligoclonal extrathymically derived T cells in a patient with atypical complete DiGeorge anomaly with the polyclonal T cells found post thymus transplantation.

Table 84.2 Use of immunosuppression for thymus transplantation

Diagnosis	Treatment*	
	No suppression # surviving/total	Suppression # surviving/total
Typical complete DiGeorge anomaly	16/21 (76%)	6/6 (100%)
Atypical complete DiGeorge anomaly	0/0	8/12 (67%)
Total	16/21 (76%)	14/18 (78%)

*Data based on 39 transplanted patients.

T cells of these infants can reject allografts, even though they do not protect against infection. If an infant has atypical complete DiGeorge syndrome, the authors begin cyclosporine treatment prior to transplantation. Cyclosporine is usually started when the diagnosis of atypical complete DiGeorge anomaly is made because the oligoclonal T cells can be very aggressive. The rash associated with these cells can be debilitating. The T cells can infiltrate the liver, leading to fibrosis. For patients with activated T cells (those expressing high levels of CD25 and HLA-DR), cyclosporine is started at least 1 week prior to the rabbit anti-thymocyte globulin therapy. Rabbit anti-thymocyte globulin is currently used in all subjects who receive immunosuppression. Both infants with typical complete DiGeorge syndrome and elevated PHA responses and all those with atypical complete DiGeorge syndrome are treated prior to thymus transplantation using three doses of the anti-thymocyte globulin at 2 mg/kg over 3 days. The rabbit anti-thymocyte globulin is generally well tolerated. The cyclosporine is usually continued in patients with atypical complete DiGeorge anomaly after transplantation until naive T cells emerge in the blood.

Fig. 84.4 Survival after thymus transplantation. Thirty of 39 (77%) patients treated with thymus transplantation survive.

OPERATIVE PROCEDURE

Thymus transplantation is an open procedure under general anesthesia. The surgeon creates furrows in the quadriceps muscle and places the slices of cultured thymus tissue individually into pockets in the muscle. The quadriceps serves as a good site because it is a relatively large, highly vascularized muscle. To allow the thymus to become vascularized in the first weeks after transplantation, steroids are limited to doses of methylprednisolone ≤ 2 mg/kg/day. Other surgeries are postponed if possible. As has been described, preparation for thymus transplantation requires careful coordination between immunologist, surgeon, and anesthesiologist.¹⁵

RESULTS OF THYMUS TRANSPLANTATION

SURVIVAL

Survival rate after thymus transplantation is 77% (30 of 39) (Fig. 84.4). Seventeen of the 30 surviving transplanted patients are 3 or more years from transplantation. No patient has died later than 6 months post transplantation. Early deaths were not related to the transplantation but were predominantly secondary to infection.

IMMUNE OUTCOMES

THYMUS GRAFT BIOPSY

Biopsies of the thymus graft 2–3 months post transplantation confirm thymopoiesis (Fig. 84.5). The biopsy illustrated was taken from a patient who was treated with immunosuppression, showing that these treatments do not prevent thymopoiesis. Specifically, the patient whose biopsy is shown had been diagnosed with atypical complete DiGeorge anomaly. This patient had $5151/\text{mm}^3$ T cells 8 days prior to transplantation; he had severe rash and lymphadenopathy. The patient was treated with cyclosporine, rabbit anti-thymocyte globulin, and steroids before transplantation, and with cyclosporine and steroids afterwards. The

biopsy, done 66 days after transplantation while the patient was still on cyclosporine, shows tissue that appears to be normal thymus with cortex and medulla (Fig. 84.5). Thus, pre-transplantation anti-thymocyte globulin and peri-transplantation cyclosporine does not prevent the development of T cells in transplanted thymus tissue.

T-CELL NUMBERS

Typical complete DiGeorge syndrome

Immune findings in the first year after transplantation vary depending on whether the infant has typical or atypical complete DiGeorge anomaly. In patients with typical complete DiGeorge anomaly, who initially have very few T cells and no rash, T cells are first observed in the peripheral blood about 3–4 months post transplantation. Naive T cells appear by 5–6 months. CD4 T cells predominate initially; CD8 T cells develop more slowly. By 2 years post transplantation, a stable total T-cell count reaches the 10th percentile in some patients, but is usually lower. CD8 numbers remain below the 10th percentile in all patients. The CD4:CD8 ratio remains >1 in all patients. A typical pattern of T-cell development is shown in Figure 84.6, panels A–C. By 9 months after thymus transplantation, T-cell proliferative responses to mitogens are normal. At that time patients are immunized with tetanus toxoid. Antigen-specific proliferative responses have developed by 2 years in all except two patients. The repertoire of TCRBV chain usage normalizes by 6–9 months. Although T-cell numbers are low for age, their function and the V β chain repertoire are normal. Composite data from these patients have been published elsewhere.²

Atypical complete DiGeorge syndrome

The time course of development of T cells in infants with atypical complete DiGeorge anomaly is similar to that in typical patients, except that such infants may have predominantly CD4 single-positive, CD8 single-positive or double-negative (CD3⁺CD4⁺CD8[−]) cells prior to transplantation. An example of a patient with a prominent CD8 single-positive population (greater than the CD4 single-positive or double-negative population) in the peri-transplant period is shown in Figure 84.6 panel D. As observed in other patients, by 4 months post transplantation the number of CD4 T cells equaled the numbers of CD8 and double-negative cells, and by 5 months CD4 T cells outnumbered the sum of CD8 single-positive and double-negative T cells. As in other atypical and typical patients 6 months post transplantation, the presence of naive CD4 T cells indicated thymic function (Fig. 84.6). In all patients treated with immunosuppression, normal proliferative responses and a normal TCRBV repertoire developed over a time course similar to that of typical patients. Composite data have been published on these patients elsewhere.³

SPECTRATYPING

Spectratyping of the TCRBV repertoire provides supportive evidence for thymic function, as polyclonal repertoires are seen in the presence of thymic function. As a polyclonal repertoire develops, naive T cells are detected in the peripheral blood by flow cytometry (Fig. 84.2 panel B). Almost all patients develop a polyclonal TCRBV repertoire within 9 months of transplantation.^{2,3} The TCRBV repertoire remains polyclonal in patients for many years, as illustrated in Figure 84.3 panel B.

Fig. 84.5 Biopsy of thymus graft. **(A)** Hematoxylin and eosin staining showing cortex and medulla. Fibrous tissue and striated muscle can be seen on the right. **(B)** Cytokeratin staining reveals lacy patterns of cytokeratin. Hassall bodies were identified on other sections. **(C)** CD1 staining shows expression of this marker of normal cortical thymocytes. **(D)** CD3 staining shows many T cells. This biopsy was obtained 66 days after thymus transplantation. As expected, there were no circulating naive T cells at this early time point. Cyclosporine had been started 14 days prior to thymus transplantation and was still being used at the time of this biopsy.

B-CELL FUNCTION

Two years post transplantation, intravenous immunoglobulin is stopped and patients are tested for specific antibody function in response to immunizations with tetanus toxoid and a pneumococcal polysaccharide vaccine (Pneumovax). All patients tested have been shown to make antigen-specific antibodies, demonstrating B-cell function. They remain off replacement immunoglobulin. Patients are then given the normal childhood vaccines, but no live vaccines are used. Future studies include plans to evaluate memory B-cell function by measuring antibody titers to secondary immunizations and the persistence of titers after immunization.

(Note: the one patient who has not developed T-cell proliferative responses against tetanus toxoid has not been tested for specific antibody function.)

SAFETY

No serious adverse events have been associated with the transplantation or biopsy procedures. In the first 3 months post transplantation three patients had mild wheezing or hypoxemia, controlled by steroids. The respiratory symptoms were associated with development of oligoclonal

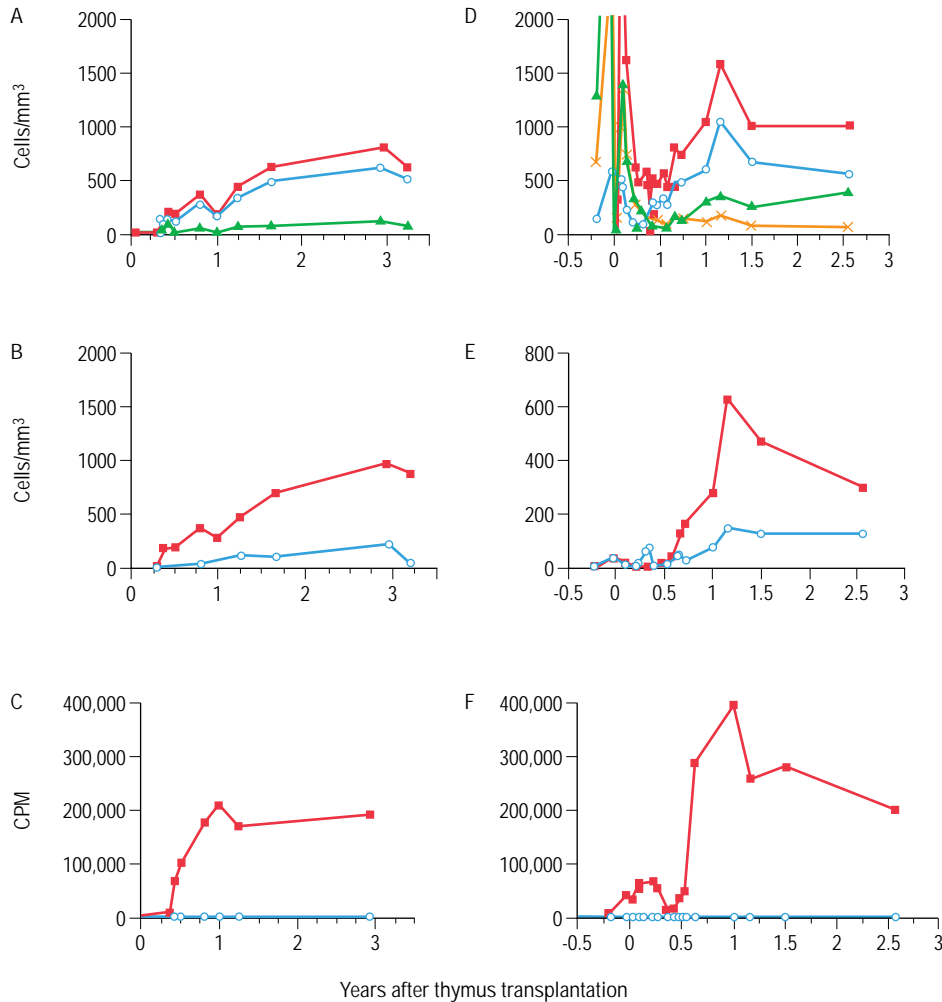

Fig. 84.6 T-cell phenotype and function after thymus transplantation. A patient with typical complete DiGeorge anomaly who was not given immunosuppression is shown in panels A–C. A patient with atypical complete DiGeorge anomaly who was given immunosuppression is shown in panels D–F. Panels A and D show absolute numbers of T-cell subsets in cells per cubic millimeter (mm³), (■) CD3, (○) CD4, (▲) CD8, (x) double negative, CD4⁺CD8⁺, T cells. Panels B and E show (■) naive CD4 and (○) naive CD8 T cell development. Panels C and F present proliferative responses in counts per minute (cpm) to the mitogen phytohemagglutinin (■) and the background of cells without mitogen (○). In panel D, the number of pre-transplantation oligoclonal T cells was 7684/mm³ prior to administration of rabbit anti-thymocyte globulin. Composite graphs for patients receiving transplants with and without immunosuppression have been published.^{2,3}

T cells after transplantation prior to the appearance of naive T cells. In one of the patients, low numbers (<500/mm³) of oligoclonal T cells had developed prior to transplantation. The respiratory symptoms only appeared after transplantation, when the T cells increased to over 1500/mm³. Many patients developed post-transplantation rashes, easily managed with topical steroids. No thymus recipient developed graft-versus-host disease. Three patients developed autoimmune-mediated thyroid disease that requires hormone replacement. These patients are discussed in detail in the next section. An additional patient developed nephrotic syndrome, which resolved after a brief course of steroids. Most patients on cyclosporine developed hypertension that required therapy until the cyclosporine was discontinued.

CLINICAL ISSUES AFTER TRANSPLANTATION

RASHES

Rashes can develop after transplantation prior to the development of naive T cells in the blood. Like the rashes seen with the development of oligoclonal T cells prior to transplantation, biopsies have been diagnosed as spongiotic dermatitis with T cells identified infiltrating the skin. The rashes are usually managed with topical steroid creams. The circulating T cells have been of recipient origin in all patients tested, although one

patient also had a small percentage of maternal T cells. No donor T cells have been associated with rashes. The rashes resolve in 3–4 months when naive T cells emerge from the thymus.

INFECTIONS

To prevent infections, patients are maintained in reverse isolation for the first year after transplantation and kept on prophylaxis for *Pneumocystis jirovecii* pneumonia for 1 year. Before prophylaxis is stopped, patients must show an antigen-specific T-cell proliferative response to tetanus toxoid. Prophylaxis for fungal or other viral infections is not used; however, specific infections are treated if they develop.

After T cells develop, infants clear infections that were present in the post-transplantation period, including infections with parainfluenza virus, respiratory syncytial virus, adenovirus, and rotavirus. Patients who contract viral infections after T cells develop are able to rapidly clear these viruses, including respiratory syncytial virus, parainfluenza virus, varicella, and adenovirus. The patient with ectodermal dysplasia is an exception. She remains unable to mount an antigen-specific T-cell response and has required hospitalization for several infections.

AUTOIMMUNE DISEASE

Three children with complete DiGeorge anomaly have developed autoimmune thyroid disease at 1–4 years post transplantation, and one also developed alopecia totalis. All continue to be followed for evidence of autoimmune disease.

LONG-TERM OUTCOME

The long-term function of the grafted thymus tissue is unknown and the focus of ongoing studies. To date, all patients have more CD4 than CD8 T cells, as expected. The T-cell receptor repertoire remains normal (Fig. 84.3). Of the 30 survivors of 39 transplants, 21 of 22 who are more than 1 year post transplantation have developed antigen-specific T-cell function. The nonresponder is the child with ectodermal dysplasia.

The patients have remained relatively healthy after transplantation. Most are growing along the growth curves at approximately the third percentile. Children who aspirate have ongoing aspiration-related respiratory infections. It is encouraging that some patients who had significant aspiration or general swallowing problems in the first few years of life have learned how to swallow, and now are taking all food by mouth.

Because this is a group of children who would not have survived without thymus transplantation, their developmental outcomes are unknown. Some children are fully functional and test at grade level, whereas others have severe developmental delays. The infants of diabetic mothers tend to perform the best functionally, and those with CHARGE have more severe delays. Quality of life and developmental outcomes are a current focus of research.

CONCLUSION

Thymus transplantation is an experimental therapy which has resulted in survival in 30 of 39 patients (77%). Survival is directly attributable to the immune reconstitution of T-cell numbers and function. These patients

CLINICAL RELEVANCE

IMMUNE AND CLINICAL RESULTS OF THYMUS TRANSPLANTATION

- >> Diverse TCR repertoire
- >> Normal CD4:CD8 ratio
- >> Good T- and B-cell function
- >> Resolution of infections
- >> Good safety profile

are being followed to learn how long the transplanted thymus will function. It is hoped that further research will permit the application of this procedure to other clinical situations in which improved T-cell function is desirable.

Immunoglobulin therapy: replacement and immunomodulation

Mark Ballow

85

INTRODUCTION

Plasma and subsequently a cold ethanol fraction of plasma that contained an enriched fraction of gammaglobulin were used over 40–50 years ago as passive immunotherapy for the treatment and protection of infectious pathogens. Drs. Robert Good in Minnesota and Charles Janeway and Fred Rosen in Boston started using this Cohn ethanol fractionation product intramuscularly (IM) as antibody replacement therapy for patients with primary immune deficiency. The goal of immunoglobulin replacement in patients with primary immunodeficiency was to provide adequate antibodies to prevent infections and long-term complications, especially pulmonary disease. This intramuscular immune serum globulin remained the principal form of therapy until 1981, when an intravenous form, i.e., immune globulin, intravenous, or IgIV, became available. Subsequently, Imbach¹ observed that thrombocytopenia resolved when immune-deficient patients were treated with IgIV. This observation led to the use of IgIV in patients with autoimmune idiopathic thrombocytopenia purpura, and an explosion on the use of IgIV as immunomodulatory therapy in a number of autoimmune disorders.

IgIV products are modified to prevent the formation of IgG aggregates to make IgIV suitable for the intravenous route. Other additions, such as sugars, amino acids, or albumin, stabilize the IgG molecules from reaggregation and also protect it during lyophilization. Treatment with solvent and detergent, pasteurization, or nanofiltration is also used as a final step for viral inactivation or removal. IgIV contains a broad spectrum of antibodies with biological activity for a number of infectious pathogens, and maintains biologic activity for Fc-mediated function. Practically, all commercial IgIV preparations are derived from ~10 000 (range 10 000–60 000) donors. Although there is no standardization for the titer of antibodies against common organisms such as *Streptococcus pneumoniae* and *Haemophilus influenzae*, each lot must contain adequate levels of antibody to potential pathogens. These products may vary slightly from each manufacturer and from lot to lot but they are generally comparable for clinical efficacy, although perhaps not tolerability. The characteristics of IgIV preparations available in the USA are reviewed in Table 85.1.

In this chapter the application of IgIV as replacement therapy in patients with primary immune deficiency and in the treatment of

KEY CONCEPTS

PROPERTIES OF IMMUNOGLOBULIN, INTRAVENOUS (IgIV)

- >> Plasma fractionation (first step) by cold ethanol/Cohn–Oncley modification (fraction II)
 - > 98% immunoglobulin G (IgG); >90% monomeric IgG
- >> Traces of other immunoglobulins, e.g., IgA and IgM, and serum proteins
- >> Addition of sugar, amino acids, or albumin stabilizes IgG from aggregation
- >> Intact Fc receptor important for biological function
 - Opsonization and phagocytosis
 - Complement activation
 - Antibody-dependent cytotoxicity
- >> Normal half-life comparable to serum IgG
- >> Normal proportion of IgG subclasses
- >> Broad spectrum of antibodies to bacterial and viral agents

autoimmune and inflammatory diseases will be reviewed. The mechanism(s) by which IgIV modulates the immune or inflammatory process in certain disease will be discussed. For a comprehensive review of all disorders treated with IgIV the reader is referred to a recent evidence-based medicine review of the topic elsewhere.¹

REPLACEMENT THERAPY WITH IMMUNE GLOBULIN, INTRAVENOUS

Several early trials in the 1980s were conducted to examine the efficacy of IgIV with IM gammaglobulin, and a comparison of low-dose with high-dose IgIV therapy. In a randomized cross-over study of either

Table 85.1 Adverse events associated with intravenous immunoglobulin therapy**Rate-related**

Chills
Headache
Back pain

^a Plasma from donor is held for 6 months until donor returns for second plasmapheresis donation.

^b Not all products use the same virus inactivation/removal steps. Each product uses 2–5 steps.

IgIV therapy between 1982 and 1997. IgIV was given at doses of > 250 mg/kg every 3 weeks with a mean serum trough level of 500–1140 mg/dl (median, 700 mg/dl). The incidence of bacterial infections requiring hospitalizations fell from 0.4 to 0.06 per patient per year. However, enteroviral meningoencephalitis still developed in 3 patients. Of 23 patients evaluated by pulmonary function tests and chest computed tomography, 3 had obstructive disease, 6 had bronchiectasis, and 20 had chronic sinusitis. The authors concluded that, although early treatment with IgIV that achieved a trough serum IgG level of > 500 mg/dl was effective in preventing severe acute bacterial infections, these levels did not prevent pulmonary disease and sinusitis. The authors suggested that more intensive therapy to maintain a higher serum IgG level (e.g., > 800 mg/dl) may improve pulmonary outcome. Most studies show that doses of IgIV of 400 mg/kg or greater have improved efficacy over lower doses in reducing the incidence of infection.²

The overall consensus among clinical immunologists is that a dose of IgIV of 400–600 mg/kg per month or a dose that maintains trough serum IgG levels > 500 mg/dl is a good starting point. Immunologists may have to rethink these levels in light of the several studies cited above.^{2,3} Generally, 400–600 mg/kg per month should raise the trough serum IgG level near the low normal range 4–8 months after initiating the infusions. On average, peak serum IgG levels increase approximately 250 mg/dl, and trough levels increase 100 mg/dl for each 100 mg/kg of IgIV infused. A rough goal to shoot for is a trough serum IgG level equal to pretreatment levels plus 300 mg/dl. Studies have demonstrated a variation in individual catabolism of infused immunoglobulin.

600 mg/kg or 200 mg/kg of IgIV in 12 patients with antibody deficiency and chronic lung disease, pulmonary function improved on the higher doses of IgIV therapy. Despite adequate serum IgG trough levels (> 500 mg/dl), patients with primary hypogammaglobulinemia and pulmonary abnormalities treated with IgIV can still progress with silent and asymptomatic pulmonary changes. Quartier and associates² performed a retrospective study of the clinical features and outcomes of 31 patients with X-linked agammaglobulinemia receiving replacement

Measurement of preinfusion (trough) serum IgG levels at 3-month intervals until a steady state is achieved, and then every 6–12 months if the patients is stable, may be helpful in adjusting the dose of IgIV to achieve adequate serum levels. For persons who have a high catabolism rate of infused IgG, or more frequent infections, infusions every 2–3 weeks of smaller doses may maintain the serum level in the normal range. The rate of elimination of IgG may be higher during a period of active infection; measuring serum IgG levels and adjusting to higher dosages or shorter treatment intervals may be required.

For replacement therapy of patients with primary immune deficiency, all brands of IgIV are probably equivalent, although there are differences in viral inactivation processes (Table 85.1). The choice of products may be dependent on the hospital or home care formulary, and the distributor availability and cost. The dose, manufacturer, and lot number should be recorded for each infusion in order to perform look-back procedures for adverse events or other consequences. It is crucial to record all side effects that occur during the infusion. It is also recommended to monitor liver and renal function tests periodically, approximately once or twice yearly.

To avoid adverse reactions in patients with active infection, especially patients with common variable immunodeficiency, the initial (first) dose should be halved (i.e., 150–200 mg/kg), and the dose repeated 2 weeks later to achieve a full dose.

To minimize cost and inconvenience, self-administration and home treatment have been used successfully. For home therapy, patients need to be selected carefully. Infusions should be done only in the presence of a responsible adult who is ready to provide assistance. Home treatment has been reported to be as effective as hospital treatment in terms of the frequency of infections, days missed from school or work, antibiotics used, and immunoglobulin level achieved. Patients receiving home treatment should be seen as regularly as patients on hospital-based treatment to monitor clinical status, liver function, and serum IgG level.

Berger and colleagues were the first to describe the use of the subcutaneous route for immunoglobulin replacement therapy in 1980.⁵ It was reported to be safe, well tolerated, and effective in achieving adequate serum IgG levels. In a multicenter study of 165 patients with primary hypogammaglobulinemia or IgG subclass deficiency those patients receiving subcutaneous infusions (27 030 at home) showed significant reductions in adverse systemic reactions compared with intramuscular or intravenous administration. Anaphylactoid reactions did not occur. Patients achieved significant increases in serum IgG after 6 months of initiating immunoglobulin therapy. The use of subcutaneous infusions instead of intravenous infusions resulted in yearly cost reductions of approximately \$10 000. Local tissue reactions to subcutaneous infusions included swelling, soreness, redness, induration, local heat, itching, and bruising. Each subcutaneous infusion requires a small portable syringe driver-type pump together with a 10–20-ml syringe and an infusion set with specialized 25–27-gauge needles. The length of the needle may have to be adjusted for the thickness of the subcutaneous tissue of each patient. Before infusion, the infusion catheter needs to be checked to ensure that there is no blood return. Infusions need to be given weekly at multiple sites or more often if needed to maintain adequate serum IgG levels. Infusion sites are usually on the abdominal wall and lateral thigh. In adults 20–40 ml can be infused into a single subcutaneous site. Before beginning home treatment, patients need to be instructed on the correct technique under close supervision and on how to recognize possible side effects. Recently, a new 16% IgIV for subcutaneous administration was approved by the Food and Drug Administration

(FDA), although any commercial IgIV preparation is suitable. Subcutaneous immunoglobulin infusion is safer, and may be less expensive, better tolerated, and preferred by some patients. It should be considered as an alternative in selected patients, especially those with adverse reactions to Ig IV with the intravenous route. More details on the subcutaneous route can be found in the review by Berger.⁵

■ ADVERSE EVENTS ASSOCIATED WITH IGIV THERAPY ■

RATE-RELATED

Typical rate-related adverse reactions with IgIV include tachycardia, dyspnea, chest tightness, back pain, arthralgia, myalgia, hypertension or hypotension, headache, pruritus, rash, and low-grade fever (Table 85.1). It seems that patients with more profound immunodeficiency or patients with active infections tend to have more severe reactions. The cause of the reactions is thought to be related to the anticomplementary activity of IgG aggregates in the IgIV in which immune complexes form between infused antibodies and antigens of infectious agents in the patient. The other possible mechanism is the formation of oligomeric or polymeric IgG complexes that interact with cell-bound Fc receptors and trigger the release of inflammatory mediators. These rate-related reactions appear to occur less frequently with the newer IgIV products. However, headaches still remain as the most frequent adverse event associated with IgIV infusions. Slowing the infusion rate or discontinuing therapy until symptoms subside may diminish the reaction. Pretreatment with aspirin (15 mg/kg per dose), acetaminophen (15 mg/kg per dose), diphenhydramine (1 mg/kg per dose) and/or hydrocortisone (6 mg/kg per dose, maximum 100 mg) 1 hour before the infusion may prevent adverse reactions.

CENTRAL NERVOUS SYSTEM-RELATED ADVERSE EVENTS

Aseptic meningitis has been reported as one of the complications of IgIV, especially with large doses, rapid infusions, and in the treatment of patients with autoimmune disease.⁶ Interestingly, this infrequently occurs in immunodeficient subjects and may be related to a lower dose of IgIV given more slowly. Symptoms, including headache, stiff neck, and photophobia, usually develop within 24 hours after completion of the infusion and may last 3–5 days. Spinal fluid pleocytosis occurs in most patients.⁶ Long-term complications are minimal. The etiology of aseptic meningitis is unclear but migraine headaches have been reported as a risk factor and may be associated with recurrence despite the use of different IgIV preparations and slower rates of infusion.

RENAL ADVERSE EVENTS

Acute renal failure is a rare but significant complication of IgIV treatment. Histopathologic findings of acute tubular necrosis, vacuolar degeneration, and osmotic nephrosis were suggestive of osmotic injury to the proximal renal tubules. Most patients (95%) had received large doses for the treatment of autoimmune disease. The majority of the cases were treated successfully with conservative treatment, but deaths were reported in 17 patients who had serious underlying conditions.

THERAPEUTIC PRINCIPLES

TREATMENT OF PATIENTS WITH PRIMARY IMMUNE DEFICIENCY WITH INTRAVENOUS IMMUNOGLOBULIN

- >> Starting dose – 400–600 mg/kg every 4 weeks
- >> Maintain trough level of >500 mg/dl or a serum immunoglobulin G (IgG) level 300 mg/dl over baseline
- >> Higher trough levels (> 800 mg/dl) may be necessary to prevent chronic pulmonary changes and enteroviral meningoencephalitis
- >> Depending on the IgG catabolism and/or control over infections, may have to decrease infusion interval to every 2–3 weeks
- >> It may take 3 months or more to achieve a steady state after a change in dose
- >> Monitor serum blood urea nitrogen, creatinine, and liver function tests every 6–12 months
- >> Keep a log of dose, manufacturer, lot number, and reactions for each infusion
- >> For patients with rate-related adverse side effects consider pretreatment with:
 - Acetaminophen
 - Diphenhydramine
 - Nonsteroidal anti-inflammatory medications
 - Corticosteroids
- >> Consider alternate route of subcutaneous intravenous immunoglobulin in patients with frequent adverse reactions

Most cases of this adverse event were associated with IgIV products using sucrose as a stabilizer. Risk factors for this adverse reaction include pre-existing renal insufficiency, diabetes mellitus, dehydration, age greater than 65 years, sepsis, paraproteinemia, and concomitant use of nephrotoxic agents. Newer IgIV products are using alternative stabilizers, e.g., amino acids instead of sucrose.

THROMBOEMBOLIC EVENTS

This adverse effect is likely due to increased serum viscosity in patients receiving large doses of IgIV for autoimmune diseases. Patients with elevated serum viscosity, e.g., cryoglobulinemia, hypergammaglobulinemia, and hypercholesterolemia, are at risk for developing a critical increase in serum viscosity with IgIV, especially high doses that predispose them to thromboembolic events. These changes can result in myocardial infarction, stroke, or pulmonary embolism. Besides cerebral infarction, reversible posterior leukoencephalopathy syndrome has also been seen in several patients receiving high-dose IgIV.

TRANSFUSION REACTION DUE TO ANTIBODIES AGAINST IgA

IgE antibodies to IgA have been reported to cause severe transfusion reactions in IgA-deficient patients.⁷ There are a few reports of true anaphylaxis in patients with selective IgA deficiency and with

common variable immunodeficiency who developed IgE antibodies to IgA after treatment with immunoglobulin.⁷ The serum levels of IgE antibody against IgA were found to correlate with anaphylaxis. Burks and coworkers⁷ recommend using IgIV preparations with very low concentrations of contaminating IgA in patients at risk for developing IgE antibodies to IgA (Table 85.2). However, this adverse event appears to be much less frequent than originally thought.

OTHER ADVERSE REACTIONS

A number of additional adverse reactions have been reported in association with IgIV infusions. These side effects are usually less common and are discussed in more detail elsewhere.⁸

SUMMARY

Immunoglobulin replacement is the mainstay of treatment for primary humoral immune deficiency. The goal of treatment is to provide a broad spectrum of antibodies to prevent infections and chronic long-term complications. The usual dose is 400–600 mg/kg per month, but this may vary individually and actually may require higher doses. A serum trough level above 500 mg/dl has been shown to be effective in the prevention of infections. However, recent studies have suggested that even higher doses and achievement of trough levels of IgG > 500 mg/dl may be desirable. Immunoglobulin can be given intramuscularly, intravenously, or subcutaneously. Intravenous administration has several advantages over the intramuscular route, and is the most preferable method. Subcutaneous administration has proved to be safe, and is a good alternative in some patients, especially those experiencing side effects by the IV route. Generally, IgIV replacement therapy is considered safe in the majority of patients. Side effects are usually mild and treatable by premedication. Good manufacturing practices, closer screening of plasma donors, testing of the source plasma, and additional viral inactivation steps have made IgIV a better and safer plasma-derived product.

THE USE OF IGIV IN AUTOIMMUNE AND INFLAMMATORY DISEASES AND MECHANISMS OF ACTION

Although we don't understand all the mechanisms by which IgIV has immunomodulatory effects (Fig. 85.1), knowledge of how IgIV exerts its actions in these diseases will allow us to define appropriate indications and schedules of administration of IgIV and to design a new-generation of IgIV products that are better able to target the immune perturbations in these autoimmune and inflammatory processes. For many of these disorders we still have to define the exact dosages that are optimal for treatment. Furthermore, for many of these diseases additional multicenter placebo-controlled clinical trials are needed to confirm clinical efficacy. A more detailed discussion of the evidence-based medicine treatment of autoimmune and inflammatory disorders can be found elsewhere.²

Table 85.2 Characteristics of intravenous immunoglobulin preparation available in the USA

Brand (manufacturer)	Manufacturing process/viral inactivation and removal steps	pH	Stabilizer/sodium	Parenteral form and final concentrations	IgA content (µg/ml)	Anti-viral steps
Gammagard S/D (Baxter Healthcare Corp.)	Cohn–Oncley cold ethanol fractionation, followed by ultrafiltration and ion exchange chromatography	6.4–7.2	Albumin, glycine, glucose 0.85–1.7% sodium	Lyophilized powder 5%, 10%	< 2.2 µg/ml (5% solution)	PEG precipitation, solvent detergent-treated
Gammagard Liquid (Baxter Healthcare Corp.)	Cohn–Oncley cold ethanol fractionation, followed by ultrafiltration and ion exchange chromatography; solvent detergent-treated 35 nm nanofiltration Low-pH incubation	4.6–5.1	Glycine Trace sodium	10% solution	37 µg/ml	Solvent detergent-treated, 35 nm nanofiltration, low-pH incubation
Gamunex (Talecris Biotherapeutics)	Cold ethanol fractionation, diafiltration and depth filtration; caprylate/chromatography	4.0–4.5	Glycine Trace sodium	10% solution	46 µg/ml	Caprylate precipitation, cloth filtration, low-pH incubation (21 days)
Carimune NF (ZLB Behring LLC)	Cold alcohol fractionation, filtration, fractionation, and depth filtration	6.4–6.8	Sucrose < 20 mg/g protein	Lyophilized powder 3%, 6%, 9%, 12%	720 µg/ml	Depth filtration, pH 4/pepsin treatment, nanofiltration
Flebogamma (Grifols)	Cold alcohol fractionation, ion exchange chromatography, PEG precipitation	5.0–6.0	D-Sorbitol < 3 mEq/l	5% solution	< 50 µg/ml	PEG precipitation, pasteurization
Octagam (Octapharma)	Cohn–Oncley cold ethanol fractionation, chromatography	5.1–6.0	Maltose, < 30 mmol/l sodium	5% solution	< 100 µg/ml	Solvent/detergent, pH4 incubation (37°C for 24 hours)
Vivaglobin (ZLB Behring LLC)	Cold alcohol fractionation	6.4–7.2	Glycine 0.3% sodium	16% liquid for subcutaneous use only	Not reported	Pasteurization

Ig, immunoglobulin; PEG, Polyethylene glycol.

Fig. 85.1 Possible immunomodulatory effects of immunoglobulin, intravenous (IgIV).

AUTOIMMUNE CYTOPENIAS

Idiopathic thrombocytopenic purpura

Idiopathic thrombocytopenic purpura (ITP) results from accelerated platelet destruction attributable to an immunologic process that could result in bleeding, which is sometimes life-threatening (Chapter 62). A number of studies in childhood ITP have shown that IgIV leads to the reversal of the thrombocytopenia. The number of days required to achieve a platelet count of $50 \times 10^9/L$ was significantly fewer in the children given IgIV than in those receiving prednisone or no therapy. IgIV as a single dose at 0.8 g/kg was similar to 1 g/kg on 2 consecutive days, but was more rapid in restoring platelet levels than intravenous anti-D or oral corticosteroids. Studies have shown that intravenous anti-D immunoglobulin is as effective as IgIV in acute childhood ITP.⁹ Anti-D IGIV therapy is

FDA-approved for the treatment of ITP in Rho(D)-positive, nonsplenectomized children, children and adults with chronic ITP, and ITP secondary to human immunodeficiency virus (HIV) infection. The main side effect from anti-D IgIV therapy is anemia due to immune hemolysis. Rarely, patients may experience acute hemoglobinemia, hemoglobinuria, acute renal failure, or disseminated intravascular coagulation.¹⁰ Anti-D IgIV therapy has the advantage of ease of administration and lower costs, and most hematologists prefer this form of therapy over IgIV.

Autoimmune hemolytic anemia

Autoimmune hemolytic anemia (AIHA) occurs when autoantibodies bind to determinants on the surface of red blood cell membranes and cause the premature clearance and destruction of erythrocytes (Chapter 62). Conflicting reports have been published regarding the efficacy of IgIV therapy in

THERAPEUTIC PRINCIPLES**TREATMENT OF IDIOPATHIC THROMBOCYTOPENIA PURPURA**

- >> Corticosteroids, oral – 1–4 mg/kg or 60 mg/m² per day until platelet recovery plus 2–3 weeks
 - For severe thrombocytopenia and impending bleed – intravenous methylprednisolone (30 mg/kg per day for 3 days)
- >> Intravenous immunoglobulin – 1 g/kg on 2 consecutive days
- >> Intravenous anti-D immunoglobulin (Rho (D)-positive individuals) – 50–75 µg/kg
- >> Anti-CD20 chimeric monoclonal antibody (rituximab)
- >> Splenectomy

KEY CONCEPTS**MECHANISMS OF ACTION OF INTRAVENOUS IMMUNOGLOBULIN IN AUTOIMMUNE CYTOPENIAS**

- >> Blockade of reticuloendothelial system
- >> Fcγ receptor downregulation
- >> Idiotype–anti-idiotype interaction between anti-platelet GPIIb/IIIa autoantibodies and the anti-idiotypic antibodies in intravenous immunoglobulin
- >> Activation of inhibitory receptor FcγRIIB
- >> Saturation of FcRn receptor to accelerate the catabolism of anti-platelet autoantibodies

patients with AIHA. Responses have been limited to patients with warm (IgG) hemolytic anemia. Patients with AIHA respond less frequently than patients with either ITP or autoimmune neutropenia. In addition, the dose of IgIV necessary to obtain a response is higher (up to 5 g/kg).

Autoimmune neutropenia

The largest experience with IgIV therapy in neutropenic states has been reported in autoimmune neutropenia of infancy. This acquired condition typically occurs in the first year of life and is characterized by an absolute neutrophil count of less than 500/mm³ (Chapter 21). In general, children with this disorder suffer from symptoms of recurrent fever and nonlife-threatening infections (gingivitis, otitis media, gastroenteritis), with recovery occurring by 4 years of age. Treatment is usually limited to antibiotic therapy. However, in children with serious infections, IgIV therapy should be considered. Therapy should be reserved for those patients with severe infections who are responding poorly or not at all to appropriate intravenous broad-spectrum antibiotic therapy.

Mechanisms of action of IgIV in ITP and autoimmune cytopenias

IgIV treatment responses in ITP are due to a blockade of the reticuloendothelial system. Sequential clearance studies of autologous radiolabeled anti-Rh(D)-sensitized erythrocytes in adults with ITP treated with IgIV showed that the increase in platelet count was accompanied by a prolonged immune clearance rate. In a different approach, children with acute ITP treated with intravenous Fcγ fragments showed a rapid increase in platelet counts. The efficacy of Fcγ fragment therapy strengthens the hypothesis that Fcγ receptor blockade is the main mechanism of action of IgIV in ITP. Other studies have suggested that Fcγ receptor downregulation or change in receptor affinity may also be involved. In addition, idiotype–anti-idiotype interactions between anti-platelet GPIIb/IIIa autoantibodies and IgIV could affect autoantibody production in ITP.

Using a murine model of immune thrombocytopenia, Samuelsson et al.¹¹ showed that the administration of IgIV prevented platelet destruction induced by a pathogenic monoclonal autoantibody. Protection was associated with the induction of the expression of FcγRIIB receptors on

splenic macrophages. This inhibitory FcγRIIB receptor was required for the protection of the animals against the pathogenic monoclonal autoantibody since disruption of the receptor by either genetic deletion or a blocking monoclonal antibody reversed the therapeutic effects of IgIV. These studies are consistent with the observation that infusion of Fc IgG fragments are effective therapy for ITP, whereas modified IgG lacking the Fc domain is less effective than intact IgG. In addition, activation of the inhibitory FcγRIIB receptor on macrophages could inhibit macrophage-mediated phagocytosis of autoantibody-coated target cells.

Recently, another mechanism has been proposed for the decrease in serum levels of autoimmune antibodies in patients treated with IgIV. The FcRn (neonatal Fc receptor) was identified as the receptor responsible for protecting IgG from catabolism in the endocytotic vesicles of the endosome, and perhaps explains the relatively long half-life of this plasma protein. IgIV may accelerate the catabolism of IgG autoantibodies by saturating these protective receptors in direct proportion to the relative concentration of exogenous plasma levels of IgG from the IgIV.¹² In a rat model of immune thrombocytopenia, Hansen and Balthasar¹³ showed that IgIV enhanced the clearance of anti-platelet antibodies in a dose-dependent manner by saturation of the FcRn receptor.

Autoimmune coagulopathies

Autoantibodies against factor VIII coagulant protein can cause an acquired hemophilia, resulting in a spectrum of bleeding complications.¹⁴ These acquired antibodies can be idiopathic, but are often found in patients with autoimmune disorders, inflammatory bowel disease, pemphigus, malignancy, and in the postpartum state. High-dose IgIV in patients with anti-factor VIII autoantibodies produces rapid and prolonged, although incomplete, suppression of inhibitor.¹⁴ Other studies showed that an F(ab')₂ fragment prepared from IgIV inhibited autoantibody activity to factor VIIIc, suggesting an idiotype–anti-idiotypic interaction between the IgIV and the autoantibodies.

KAWASAKI SYNDROME

Kawasaki syndrome (KS) is an acute multisystem disease of unknown etiology that primarily affects infants and young children (Chapter 58). Although KS occurs worldwide in children of all racial groups, it is most

CLINICAL PEARLS

CLINICAL FEATURES OF ACUTE KAWASAKI SYNDROME^a

1. Fever of at least 5 days' duration
2. Presence of at least four of the five following conditions:
 - >> Bilateral nonexudative conjunctival injection
 - >> One of the following changes in the oropharynx: injected or fissured lips, injected pharynx, or 'strawberry tongue'
 - >> One of the following extremity changes: erythema of the palms or soles, edema of the hands or feet, or periungual desquamation
 - >> Polymorphous rash
 - >> Acute nonsuppurative cervical lymphadenopathy
3. Cardiovascular abnormalities:
 - >> Myocarditis, arterial aneurysms, pericarditis, aortic or mitral regurgitation, ventricular arrhythmias
4. Other:
 - >> Arthralgia and arthritis, urethritis with sterile pyuria, hydrops of the gallbladder, diarrhea, vomiting, or abdominal pain, sensorineural hearing loss

^a Points 1 and 2 constitute the primary diagnostic criteria for Kawasaki syndrome

prevalent in Japan and in children of Japanese ancestry. Although the acute illness is generally self-limited, coronary artery abnormalities related to a generalized inflammation and immune activation of small and medium-sized blood vessels develop in up to 25% of untreated patients. Although the etiology remains unknown, the clinical features and laboratory findings suggest an infectious or postinfectious process.

In a multicenter randomized trial in the USA, the effects of IgIV 400 mg/kg per day for 4 consecutive days plus aspirin were compared to aspirin alone. The results showed that 2 weeks after onset of therapy, coronary artery abnormalities were present in 23% (18 of 78) of children in the aspirin group, as compared with only 8% (6 of 75) in the IgIV plus aspirin group. Seven weeks after enrollment, coronary abnormalities were present in 18% (14 of 79) of children in the aspirin group and in 4% (3 of 79) of the IgIV plus aspirin group. In a follow-up study, the efficacy of a single infusion of IgIV 2 g/kg was compared with 400 mg/kg for 4 consecutive days.¹⁵ The relative prevalence of coronary artery lesions, adjusted for age and sex, among patients treated with the 4-day regimen was almost twice as high as those patients treated with the single-infusion regimen. Laboratory assessments of acute inflammation in the single-infusion group showed a more rapid trend toward normal. Lower serum IgG levels on day 4 were associated with a greater degree of systemic inflammation and with a higher prevalence of coronary abnormalities. A meta-analysis of published studies on the treatment of KS showed a dose response for IgIV with a threshold for decreased incidence of coronary artery aneurysm with IgIV dosages of > 1 g/kg, and that low-dose aspirin (80 mg/kg) was comparable to high-dose aspirin (> 80 mg/kg) when combined with high-dose IgIV.¹⁶ More recently, a retrospective

analysis of retreatment of patients who remained febrile after IgIV (1 g/kg) suggested improved outcome with a higher dose of IgIV (2 g/kg), although these findings need to be confirmed prospectively.

KS is associated with marked activation of T cells and monocytes-macrophages.¹⁷ Based on the immunologic and clinical features overlapping with a bacterial toxic shock-like syndrome, studies were carried out to determine if KS is associated with exposure to a superantigen such as a bacterial toxin.¹⁸ The mechanism by which a superantigen can lead to the clinical manifestations of KS remains to be elucidated. However, acute KS is associated with marked immune activation and increased circulating cytokine levels, including interleukin-1 (IL-1), IL-6, IL-8, IL-4, IL-10, and tumor necrosis factor- α (TNF- α).¹⁸ Some of these cytokines elicit proinflammatory and prothrombotic responses by inducing the expression of leukocyte adhesion molecules, which attach inflammatory cells to vascular endothelial cells. The expression of endothelial leukocyte adhesion molecules has been demonstrated in acute KS and its downregulation correlates with favorable response to IgIV treatment.¹⁷ In contrast, patients treated with aspirin alone show prolonged T- and B-cell activation. The magnitude and persistence of proinflammatory cytokine synthesis have been reported to constitute a risk for the development of coronary artery abnormalities.

IgIV has been shown to contain high titers of specific antibodies that inhibit the activation of T cells by staphylococcal and streptococcal superantigens. These findings may account for the observation that treatment of acute KS with IgIV results in a marked reduction of macrophage and T-cell activation.¹⁸ In this regard, the efficacy of IgIV in suppressing the immune activation associated with KS, and more importantly, its ability to prevent the development of coronary artery abnormalities in this illness may relate to the neutralizing antibody activity of IgIV against these bacterial toxins.¹⁷ The finding that a threshold dose of IgIV is needed to decrease signs of acute inflammation in KS and that some patients require retreatment suggests that IgIV contains variable anti-toxin titers. In addition, toxin neutralization is not likely the only beneficial effect of IgIV in KS. A recent report of the use of different brands of IgIV in patients with KS showed differences in response rate and the development of coronary artery aneurysms.¹⁹ The authors attributed these differences in efficacy to differences in manufacturing processes between the different products that may affect the Fc portion of the IgG molecule. As noted for ITP, the Fc portion may activate the immune-modulating Fc γ RIIB receptor. Other potential mechanisms of IgIV include immunomodulation of cytokine production or cytokine effects, resulting in the inhibition of endothelial cell activation. Gill and coworkers²⁰ reported that IgIV inhibits leukocyte recruitment into inflammatory tissues by inhibiting selectin and integrin function. New insights into the pathogenesis of KS will likely help elucidate the mechanisms by which IgIV reduces coronary artery vasculitis.

AUTOIMMUNE NEUROMUSCULAR DISEASES

The autoimmune neuropathies represent the largest group of autoimmune diseases that are treated with IgIV (Chapters 64-66). In fact, autoimmune neurological diseases account for approximately 30-40% of all IgIV use for 'recommended off-label' indications. The autoimmune neuropathies fall into four categories: (1) the *inflammatory demyelinating polyneuropathies*, which include the Guillain-Barré syndrome (GBS); chronic progressive or relapsing remitting inflammatory demyelinating polyneuropathy (CIDP), and multifocal motor neuropathy; (2) the

autoimmune neuromuscular junction defects such as myasthenia gravis (MG) and Lambert–Eaton syndrome; (3) the *inflammatory myopathies*, which include dermatomyositis (DM), polymyositis, and inclusion-body myositis; and (4) the *central nervous system diseases* such as multiple sclerosis, stiff-person syndrome, and Alzheimer's disease. More information about the use of IgIV in the autoimmune neuromuscular diseases can be found in reviews on this topic elsewhere.^{21, 22}

THE INFLAMMATORY DEMYELINATING POLYNEUROPATHIES

Although the etiology of GBS is not known, the pathogenesis of GBS is thought to be an autoimmune process with destruction of peripheral nerve myelin. Patients present with a rapid ascending paralysis, often with autonomic and sensory involvement. Most cases are preceded by an upper respiratory or diarrheal illness. *Campylobacter jejuni* is the most common bacterial pathogen isolated from the gastrointestinal tract. About 80% of GBS patients recover satisfactorily from their disease. The principal approach to the treatment of these patients has been supportive therapy. As summarized by Delakas,²¹ a Dutch group reported on a randomized trial comparing plasma exchange and IgIV (0.4 g/kg per day for 5 days). Muscle strength improved by one grade in 34% of those treated with plasma exchange compared to 53% receiving IgIV; median time to improvement was 41 and 27 days, respectively. Also in a large European, multicenter randomized trial of 379 adult patients with GBS, the efficacy of inflammatory demyelinating polyneuropathy (50 ml/kg for 5 exchanges) was compared with IgIV (0.4 g/kg for 5 days), and with a combination regimen of plasma exchange followed by IgIV. There were no differences between any of the treatment groups for the major and secondary outcome measures. Both the French and North American studies concluded that plasma exchange in GBS is most effective when carried out early in the course of the disease. Early recognition and treatment may thus be important for the long-term prognosis of patients who have severe disease and rapid progression.²³ Because IgIV treatment is more readily available, easier, and has fewer side effects than plasma exchange, this modality of treatment might be more useful in GBS patients at the early stage of disease, especially in patients who have evidence of rapid progression, older age, or a history of diarrhea.²³ Several studies looked at optimal dosing that showed that IgIV was most beneficial when given in a full dose of 2 g/kg, especially in patients who needed ventilatory assistance. In children with GBS IgIV therapy was equally as effective as plasmapheresis, and associated with fewer complications.²⁴

CIDP is an inflammatory neurologic disease resembling GBS, which may cause prolonged disability.²² As with GBS, an immune-mediated mechanism for myelin destruction has been postulated in CIDP. In a double-blind placebo-controlled cross-over study of IgIV (0.4 g IgIV per kg per day for 5 consecutive days), all IgIV-treated patients improved on day 8 after therapy; in contrast, none of the patients receiving placebo improved. In other studies comparing IgIV with steroids or plasma exchange, improvements in neurological disability were similar, although the administration of IgIV was less complex than plasma exchange, and IgIV had fewer adverse effects compared to steroids. However, not all patients respond to IgIV and certainly not all patients respond to the same extent. Improvement is usually noticed within the first week of treatment and may last for 6–8 weeks. Many patients can be maintained on IgIV pulse therapy of 1 g/kg body weight prior to the expected relapse. A beneficial response to IgIV was found to be more likely in

patients with acute relapse or with disease of 1 year or less. Patients with sensory signs responded less well. Children with CIDP also respond well to IgIV. Patients with an IgM monoclonal paraprotein associated with a demyelinating peripheral neuropathy may also have a modest response to IgIV treatment. In contrast, patients with a paraneoplastic neurological syndrome and antineuronal autoantibodies (anti-Hu and anti-Yo) did not respond to IgIV therapy.

Multifocal motor neuropathy shares some similarities with GBS and CIDP.²¹ This disorder is characterized by progressive distal, asymmetric limb weakness with a conduction block of motor but not sensory nerves. However, several open-label studies and a controlled trial showed that multifocal motor neuropathy responds to IgIV therapy. Of note, the beneficial effects of IgIV are often not long-lasting.
